DOCTOR-FACTORIES.—“There must be much admirable medical teaching in the United States. The account of American surgery given lately in our columns by Mr. Erichsen, and the highly-cultivated intelligence and information of many of our American visitors, are proof enough of this. There are, too, many admirable schools from which reliable diplomas emanate,—such as the Harvard University, Boston; Yale University, Massachusetts; the New York University; the New York Columbia University; the Bellevue Hospital; the Philadelphia University (*sic*); the Virginia University; the Louisiana University; the Michigan University; etc., etc. But there would appear to be, in the States, a most deplorable multiplication of colleges and schools purporting to teach medicine and to grant diplomas, which can be no real guarantees of education to the public, and which bear no comparison even with the lowest of our British qualifications. Every State in this matter legislates for itself, and the result is, as we have said, a terrible multiplication of ‘doctor-factories.’” — *London Lancet*.

THE modest gentleman at the head of the *Clinic*, who claims so pertinaciously to be the ablest editor in this country, takes the editor of the *Times* to task very severely for stating, in reply to his assertion that the *Clinic* offers more readable matter than any other journal in the country, that the *Times* contains nearly twice as much matter as the *Clinic*, affirming that it has in it only three pages a week or twenty-five per cent. more than has his periodical. The truth is, the *Times* has four and one-half pages more, and uses a smaller type. If our truth-loving critic will take the trouble to count the lines, he will find that the *Times* of the week of his article contained considerably over fifty per cent. more than did the *Clinic*. It is generally considered allowable for a publisher to state what he pleases about his wares, but this vaunting of his own productions by an editor does not seem to us very good taste.

LIFE AND DEATH IN PARIS AND LONDON.—The municipal statistics of Paris just published show that from a population of 1,851,792, there were born in 1873 55,905 children,—28,244 boys and 27,661 girls,—being an average of 153 births a day, and a proportion of thirty children to every 1000 of the inhabitants. London, of which the population (3,400,761) is not double that of Paris, shows more than a double amount of births in the same year. There were 41,732 deaths in Paris in 1873, comprising 21,380 males, and 20,352 females, being an average of 114 deaths daily, and a proportion of 22.54 to every 1000 of the inhabitants. Here again London contrasts favorably with Paris; the

number of deaths registered in 1873 having been only 76,634 in a population of more than double the amount of that of Paris.—*London Medical Record*.

NOTES AND QUERIES.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Whilst examining, the other day, a case of severe lacerated wound of the scalp, where I had reason to fear from the symptoms that though no fracture with depression of the skull existed, yet a fissure or a stellated fracture might, a paper by Assistant-Surgeon —, U.S.A., on the use of an infant's ring in preventing pus from being forced into the surrounding healthy tissues by Esmarch's bandage, while excising dead or carious bone, came to my recollection, and I found that, by applying one of these rings round the wound, I could examine the part of the skull laid bare much more completely and satisfactorily, as there was no oozing of blood from the edges of the wound.

If this suggestion has been made before, I beg to say that, having been travelling and separated from my books and papers for some time, I have not seen it, and now offer it as a natural and simple deduction from the suggestion of Assistant-Surgeon —, U.S.A.

Yours faithfully,

JAMES M. JANES, M.D., M.R.C.S.E.

DENVER, COLORADO, January 5, 1875.

PHILADELPHIA, 27 January, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Permit me to correct an error which appears at p. 270 of the current volume of your journal.

The case whose history begins with the words “He was called to see a patient August 1, 1873,” was reported by Dr. D. M. Barr, and not by

Yours, very respectfully,

WILLIAM GOODELL.

OBITUARY.

EXPIRED, in New Berlin, Pennsylvania, January 19, 1875, Dr. Joseph R. Lotz, in the seventy-sixth year of his age.

Dr. Lotz attended lectures at the University of Pennsylvania when such Professors as Physick, Hare, Chapman, and others gave celebrity to that institution. Until the infirmities of age compelled him to “take off the harness,” he was ever diligently engaged in the labors of an immense practice, in which he attained great eminence. He was a skilful surgeon, a bold and brilliant operator, and his services in this department were often demanded far and near. He was the inventor of an instrument for the cure of artificial anus, well spoken of in their lectures by Professors Gibson, Smith, and Mütter.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

THE next conversational meeting will be held at the hall of the College of Physicians, Wednesday, February 10, at 8 o'clock P.M.

Dr. George Hamilton will read a paper: subject, “Remarks on the Diagnosis, Prognosis, and General Management of Typhoid Fever.”

The medical profession in Philadelphia are cordially invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JANUARY 26, 1875, TO FEBRUARY 1, 1875, INCLUSIVE.

BAILY, J. C., SURGEON.—Granted leave of absence for one month, provided he furnishes a suitable substitute during his absence. S. O. 11, Department of the South, January 27, 1875.

BACHE, DALLAS, SURGEON.—Temporarily assigned to duty at Baltimore, Maryland, as Attending-Surgeon and Examiner of Recruits. S. O. 16, A. G. O., January 26, 1875.

JACKSON, D., ASSISTANT-SURGEON.—Assigned to temporary duty at Fort Concho, Texas. S. O. 10, Department of Texas, January 18, 1875.

SEMGIS, B. G., ASSISTANT-SURGEON.—Instead of complying with S. O. 124, of 1874, from these Headquarters, to report to the Commanding Officer of the Presidio of San Francisco, for such duty as he is able to perform. S. O. 10, Department of California, January 23, 1875.

The Medical Examining Board in session in San Francisco, California, is dissolved, and the members thereof will rejoin their proper stations. S. O. 17, A. G. O., January 28, 1875.

SATURDAY, FEBRUARY 13, 1875.

ORIGINAL COMMUNICATIONS.

ON THE SPASMODIC DISEASES OF STUMPS.

BY S. WEIR MITCHELL, M.D.

I HAVE had very numerous chances of studying the curious and most interesting maladies of stumps, and have often wondered that no surgeon has been at the pains to write a monograph on stumps and their diseases. I have attempted to do something in this direction in my book on "Injuries of Nerves," but far more remains to be done in a purely surgical point of view. To the mere operator, to the physiologist and psychologist as well as to the physician, these maimed limb-remainders are full of interest. Such a thing in fact as a perfectly healthy stump, which is normally sensitive, does not twitch, calls up no memory of lost toes or fingers, and is not affected by weather, I might almost assert does not exist. The stump, in fact,—and I may say here that we have no technical name for it, and one is wanted,—the stump is throughout life a pathological part. It has a pathology rather than a physiology, so remarkable are the conditions of its being,—so rare is it to find it quite like other parts.

Among the peculiarities of stumps is a liability to spasm of the muscles, which assumes at least three distinct forms, two of which I have already described. One of these is the chorea of stumps,—a strange affection (see "Injuries of Nerves," p. 364), in which the limb is kept constantly in the most active motion. Since I first delineated this disease from the case of Col. P., who is still its victim, I have met with other examples more or less remarkable, but none so striking as his. I am satisfied that *early* section of the nerves would cure it; but so far I have had no chance to test the value of my belief.

The second form of spasm is usually but not always connected with pain in, or, rather, referred to, the lost part, and with sense of spasm in that part. There is a quivering and twitching here and there in the severed muscles of the stump. It comes and goes, in some is rarely absent, in others is seen only when there is pain, and in all is worse when the watery winds prevail. As to this point I have long ceased to doubt, and lately one of my patients has most absolutely confirmed my belief. This gentleman has kept a record, reduced to curves, of the thermal, barometric, and hygrometric states of the air, of the winds, and even of the ozone, and by following the lines of the pain-curve it is possible to see just what atmospheric states favor in him the condition—pain. This curious and valuable record, kept by a man of great accuracy and remarkable scientific endowments, I shall before long make public. Suffice it now to say that it proves most perfectly the capacity of the stump to indicate by pain and spasms the approach of winds which bring rain, and not alone the east wind, which some of my patients insist is the only one thus competent.

In some cases the twitching is only in one or more muscles, not in all, and, when limited, is in certain cases useful, because, as the neuro-muscular distribution is rarely anomalous, and as the seat of pain in the lost part is not always distinct, we can tell by the muscles concerned in spasm what main nerve-trunk must be cut to relieve the pain.

As a more innocent malady, without pain as its companion, this local twitching of stump-muscles is very common. I have said that there were three forms of stump-spasm; but there is one more which is excessively rare, and is apt, when it does come, to follow some sudden injury to a tender stump.

This form of spasm is not so much in the stump as in the muscles of the same limb which are a little remote and have not been severed by the knife. It consists in a single violent tonic contraction three or four times a day,—a spasm which is like a cramp, and is horribly painful. I have seen this but twice. In one case the deltoid was concerned, and in another the short intra-pelvic flexors of the thigh. The attacks in both followed a blow; in the first case on the stump, in the second on the groin (a thigh-amputation high up). In both, relief was obtained by ice-dressings and leeching.

My last form of stump-spasms is altogether peculiar, nor can I find it described elsewhere; but, as I have said, this is not surprising, because the surgical literature of stumps is disgracefully small and incomplete.

In some cases of myelitis, in some instances of spinal sclerosis, and in rare hysterical conditions, the affected limb is liable to become suddenly and often most violently convulsed, the spasms in certain instances extending to the rest of the body, and in others remaining confined to the member in which they began. These attacks appear in some cases to be spontaneous, or, rather, to be discharges of force from motor ganglia in abnormal states. In other examples they are brought about by any cause which, like a blow or tickling, operates from without through the afferent nerve-tracks. This description applies equally to the stump-spasms I am about to describe.

I saw the first of my cases during the war, and shall describe it from memory, as I have mislaid my notes.

A sergeant lost his leg from a Minié-ball, which necessitated an amputation above the right ankle. At least three months later, he began to have pain in the stump and absent foot. It was not severe. The pain was associated with twitches of the stump-muscles. About nine months from the date of amputation he received a fall on the stump, bruising it badly. Some days after, while washing it with cold water, it became agitated, and finally convulsed, the extensors and flexors acting irregularly. The attack lasted a few minutes, and was the first of many such, which increased in severity until any rough touch brought on a fit that at length resulted in twitches of the right pectoral muscles; but at no time were there any marked cerebral symptoms. The patient soon after passed from under my care. Among the hundreds of stumps I have seen since, I have met with a number of like cases.

A remarkable example was seen in a gentleman æt. 50, whose right hand was injured, and, a week later, removed at the lower third of the fore-arm. He was never free of pain, or of the consciousness of the presence of the absent part, and about six weeks after its loss began to have slight attacks of stump-spasm. They increased in severity, and were usually worst in wet weather. The bad attacks began with slight twitching, which, increasing in severity, within a minute involved the fore-arm and arm, and even the deltoid, pectorals, and trapezius. On one occasion the face, he stated, was distinctly drawn to the right, and he had a slight sense of disturbed equilibrium. As his health improved,—and it had been very feeble,—the fits lessened in number, and were less grave. Prolonged use of dry cold to the stump in rubber bags, with hypodermic injections of atropia in the stump, iron, and cod-liver oil finally relieved him, and he has now, I believe, been for a year free from any bad fit. In another case, an officer who lost his thigh at the lower third had neuralgia and stump-spasms, chiefly owing to a long bout of obstinate ague. The pain came first, and when present the least careless friction or blow on the stump sent it off into a furious shaking fit, which much increased the pain. The cure of the ague and a long residence in a mountain climate relieved both troubles, but, I believe, did not quite cure either.

Sometimes the fits are altogether painless. I was examining, two weeks ago, a stump, when suddenly it went off into a violent and almost grotesque series of flexions and extensions, moving so fast that I could scarcely follow with my eye its rapid movements. There was little pain at the time, and this was a type of the more common form of this malady.

It is hardly necessary to describe it further. The attacks are rare in many cases, and I have seen it pass beyond the limb in but two. Nearly always it occurs in stumps which are painful or tender. It lasts but a few minutes, and, like some of the spinal epilepsies of Brown-Séquard, can often be arrested by holding the limb or forcibly flexing it. It almost depends in a few cases on loss or lowering of general tone of health, and in these gets better as the depressing causes are remedied. In others it is found to co-exist with perfect systemic health. I have not found that bromides relieve it, but cold to the stump and atropia-injections act better. I presume that nerve-section used early would be effectual.

I never saw a case arise very soon after amputation. I suspect—indeed, I believe—that neural irritations resulting in inflammation or sclerosis of the trunks are the peripheral exciting causes, and that these finally act on their related groups of motor ganglia to produce in them an over-readiness to discharges of motor nerve force. It has been shown that amputations bring about in the spinal cord distinct sclerotic or atrophic conditions which may possibly have a share in the results described; but the fits sometimes occur too soon after amputation to admit of this explanation, and that of peripheral irritation seems the more probable one.

AN OBJECTIVE NOISE IN THE EAR, ACCOMPANIED BY SPASMODIC RETRACTION OF THE MEMBRANA TYMPANI AND OF THE VELUM PALATI.

BY CHARLES H. BURNETT, M.D.,

Aural Surgeon to the Presbyterian Hospital, and Surgeon-in-Charge of the Philadelphia Infirmary for Diseases of the Ear.

I DESIRE to place on record a short account of the above-named curious affection, occurring in a Japanese lad 18 years old, sent to me by Dr. R. M. Girvin, of West Philadelphia. The patient came under my care for treatment of a chronic suppurative inflammation of the left middle ear, with perforation of the membrana tympani, the result of acute inflammation incurred last July by diving in salt water. The patient complained only of the left ear. He did not draw my attention to the right ear, affected by the spasm about to be described, but, while inspecting the right ear for purposes of comparison, I heard distinctly a noise resembling the snapping of the finger-nails, emanating from it. The snapping was most audible when the ear of the listener was placed close to the right ear of the patient, but it could be distinctly heard ten feet from the ear from which it came. It was also heard very distinctly when the ear was placed near the right nostril of the patient. It was not, however, audible in the left ear of the patient, neither by placing my ear on his ear, nor by the use of the auscultation-tube. Inspection revealed a thickened and reddened condition of the right membrana tympani; and the patient stated that he had had, some years previous, discharges from the right ear, and I found that the hearing was defective in it.

The snapping sounds began in it last summer, one week after the acute inflammation in the left ear. At the first examination, November 25, 1874, by simple inspection I could detect no motion in the membrana tympani at each snapping, but in the course of a month, the thickening of the drum-head becoming less, I could detect at each snapping sound a very slight retraction of the drum-head at its antero-superior quadrant. Before I could thus see any motion in the drum-head by simple inspection, I placed a small glass manometer devised by Politzer, with its capillary calibre, one millimetre in diameter, filled with colored water, into the meatus of the right ear, also filled with water, the two columns of water being hermetically joined by an india-rubber stopper on the manometer. The column of water thus brought into contact with the membrana tympani showed a negative fluctuation of one-half millimetre at each snapping sound, thus demonstrating a retraction of the membrana tympani too small to be seen at that time by inspection, but since apparent upon close and attentive inspection. The drum-head moved readily under the Siglé's pneumatic speculum.

The examination of the fauces revealed an elevation and retraction of the velum palati with each snapping sound in the ear and each manometric depression. The negative fluctuation,—i.e., depression in the manometric column,—amounting to one-half millimetre, occurring at each snapping

sound in the ear, was entirely distinct from a very slight positive oscillation in the same column at each cardiac impulse. The latter could not always be discerned.

Deglutition, respiration, and speech exercise a marked influence over the spasmodic condition already described. The patient stated that deglutition and rapid respiration increased the frequency of the snapping noise in the ear, but that when he held his breath, the spasms (in the velum palati) and the snapping noise in the ear ceased entirely, to begin again with renewed respiratory acts. I found, indeed, that so long as the patient held his breath neither he nor I could hear any snapping, nor could I detect any spasmodic movement of the velum; but they all recurred as soon as the patient resumed his breathing. During ordinary respiration I counted twenty spasms in a minute, which appeared to be the average number; but with a voluntarily increased number of respirations the number of snappings and spasms of the velum rose to thirty in a minute. During continued speech no snappings occur.

These peculiar snappings are not in regular succession, nor synchronous with the respirations. Two or three snappings usually occur in quick succession, are followed by a pause, then there are several more, thus completing twenty in a minute. These noises interfered so much with the hearing in the ear where they occurred that the patient, when specially desirous to increase his hearing, held his breath, which, as already stated, would control the spasms. I found by testing with a watch, audible normally sixty inches, that the hearing was indeed influenced by the spasms and their temporary cessation, as the patient had stated; for the watch, audible to him only on contact during the spasms, was heard two inches when they were arrested by holding his breath.

Tuning-forks held before the ear appeared to the patient to rise in pitch at each spasm. The rise in the note was well imitated by the patient. This altered pitch we are prepared to hear of, because at each spasm the drum-head is retracted, and rendered, by this increased tension, more sensitive to high than to low notes, and hence the ear perceives the higher to the exclusion of the lower partial tones of the tuning-forks.

The snapping sounds, but not the spasmodic elevations in the velum, can be arrested in two other ways. By throwing the patient's head back as far as he could get it; the spasms in the velum palati went on with the usual intervals, but neither the patient nor I could hear any snapping.

I could also arrest the noise by pressing my finger firmly against the velum, and pushing it upward towards the pharyngeal opening of the right Eustachian tube. While I could still feel a powerful twitching with the usual intervals of repose of the muscular structures thus pressed upon, all snapping noise ceased.

Pressure upon the left half of the velum palati and mediately upon the pharyngeal opening of the left Eustachian tube revealed no twitching in that region, nor did it influence in any way the

spasms and noises on the opposite side of the pharynx and in the right ear.

Johannes Müller was disposed to attribute all such cases of objective entotic noises, resembling the snapping of the finger-nails, to clonic spasms of the tensor tympani muscle; but Politzer and Luschka, independently of each other, and about the same time (1862), proved conclusively that many cases of such noises previously ascribed to spasmodic twitchings in the tensor tympani were really due to a spasmodic contraction of the muscles of the velum palati, *producing a sudden separation of the anterior from the posterior wall of the pharyngeal portion of the Eustachian tube.*

This hypothesis has been substantiated by cases reported by Boeck,* Schwartz,† Politzer,‡ A. Schrapinger,§ Küpper,|| and others.

In Dr. Küpper's case, the spasms, amounting to one hundred and forty in a minute, were temporarily arrested by pressure at the base of the tongue, and partially relieved—i.e., diminished in frequency—by pressure on the lesser occipital nerve near the insertion of the sterno-cleido-mastoid muscle; but they were in no way connected with the act of respiration or with the circulation.

Moos relates a case of retraction of the membrana tympani with objective noise in the ear, occurring only at deglutition (*Archives of Ophthalmology and Otology*, vol. ii.).

The quality of the objective noise in these cases is universally likened to the snapping of the finger-nails. Its cause is without doubt due to the sudden separation of the anterior from the posterior wall of the pharyngeal portion of the Eustachian tube, and *not to any spasm in the tensor tympani muscle.*

This would seem to be corroborated by the fact that this peculiar objective noise in the ear is accompanied by spasm of the velum palati more frequently than by any other one symptom. The cases where it has not occurred, or where no mention is made of it, are very rare. Positive knowledge as to its absence is gained in only one case (Schwartz, *Arch. f. Ohrenheilk.*, Bd. vi., 1870). Again, the fact that the noise in my case is so distinctly audible at the nostril of the affected side, seems to indicate that its cause lies in the nasopharyngeal space at the mouth of the Eustachian tube, and not purely in the tympanic cavity. Doubtless the retraction of the membrana tympani seen in some of these cases is due to a spasm of the tensor tympani.

Treatment.—The whole number of these cases is so small, and the individual experience respecting them is so limited, that our knowledge respecting the therapeutics of this variety of aural disease is of course very meagre. So far as we can glean an opinion from what has been written concerning the treatment of these cases of clonic spasms, the induction current has effected the only apparent relief and cure (Schwartz, Politzer, and Boeck). In my

* Archiv f. Ohrenheilkunde, Bd. ii.

§ Sitzb. der Oestreich. Academie der Wissensch., Bd. lxii. Section 2, Oct. 1870.

|| Archiv f. Ohrenheilk., N. F., Bd. i.

case and in many others the snapping has occasioned so little annoyance to the patient that treatment for it has not been desired, which one is ready to infer from the fact that these cases have usually been discovered accidentally by the physician to whom the patient has applied for relief from other aural troubles.

EXPERIMENTS ON DIGESTION.

BY ROBERT M. SMITH, A.B.,

One of the Assistants to the Professor of the Institutes of Medicine in the University of Pennsylvania.

THE following experiments were made upon the contents of the stomach of a criminal (Heidenblut), previously of good health, who was executed while digesting a hearty breakfast of hard-boiled eggs, bread and butter, and coffee. When his stomach was examined, some two hours after his death, it was found to present the usual redness of the organ whilst digesting, more deeply marked, however, in the great cul-de-sac and along the greater curvature towards the pylorus, the latter being due to the semi-erect position in which the body was placed after death having caused the gravitation of the contents to these parts. Over the portion of deepest redness the mucous membrane was soft and pulpy, and the blood-vessels more apparent than in other places; incipient digestion of the mucous coat had evidently taken place, owing to the action of the solvent juice upon it. The mucous coat, after the organ was emptied, was somewhat plicated from the contraction of the muscular walls. The contents, which nearly filled the organ, were of a grumous consistence, somewhat yellowish in color, and of decidedly acid reaction to test-paper. They contained portions of undigested albumen, and a large amount of glucose as discovered by Trommer's test. Microscopical examination of the contents revealed the presence of numerous oil-globules, granular matter, and a large number of partly broken-up starch-granules; the presence of starch was further certified by its presenting the usual reaction with iodine.

These contents of the stomach were now subjected to filtration in a vessel which had been previously washed with distilled water and tested with nitrate of silver, and found to be perfectly free from all chlorides. Upon the addition of nitrate of silver to the *filtrate* thus obtained, a dense white precipitate was thrown down; but upon adding a small quantity of chemically pure nitric acid, a *considerable* portion of the precipitate was re-dissolved, so, perhaps, justifying the supposition that it was not entirely composed of the chloride of silver, which is perfectly insoluble in nitric acid, but partly of the lactate, or of some other salt of silver which is soluble in nitric acid.

This filtrate, after having shown an acid reaction to litmus-paper, was carefully poured through a chemically clean funnel into a chemically clean glass retort, so that no particles of the fluid could adhere to the neck of the retort and be carried over mechanically in the process of distillation. The

retort was now slowly heated in a sand-bath to a little *below* the boiling-point of the fluid, so as to insure the passage of volatile matters alone into the condenser; by this means—viz., of keeping the fluid constantly in a state of incipient ebullition—it was impossible that any non-volatile salt or matter of any kind could be carried over in the spray of the distilling fluid. After this heat had been kept up for a little less than an hour, there was condensed in the receiver about a drachm of a yellowish fluid of a watery consistence. This distillate showed a distinctly acid reaction to test-paper, and the question now to be determined was whether this acidity was due to free hydrochloric acid, as has been generally supposed by physiologists, or to the presence of some other acid.

To determine whether any free hydrochloric acid was present, two drops of a strong solution of nitrate of silver were added to about thirty drops of the distillate, when a decided precipitate, resembling the chloride of silver, was visible; upon adding a single drop of chemically pure nitric acid, this white precipitate was immediately re-dissolved. If this had been a chloride of silver which was thrown down, nitric acid would have been entirely unable to dissolve it. But it is known that nitric acid will dissolve the white lactate of silver, and it seemed from this fact justifiable to suppose that the precipitate might be that of the lactate of silver, as it was proven not to be a chloride.

To determine the truth or falsity of this supposition, about thirty drops of the distillate were added to an equal quantity of fresh milk, when no effect was observed; but upon boiling the milk a decidedly flocculent appearance was distinctly visible, and upon allowing the fluid to stand for an hour or two it became so solid that the test-tube could be turned on its side without the contents flowing out. It is known that lactic acid will produce this effect under these conditions, while if the acid had been muriatic the casein of the milk would have coagulated without boiling. The distillate also coagulated the albumen of a fresh egg. To determine whether these results were obtained by the action of some new substance formed in the process of distillation, or whether such a substance existed in the fluid before distillation, part of the *original filtrate* was added to fresh unboiled milk, when no coagulation was observed; but upon boiling the milk a very decided coagulation was perceptible, and upon allowing the fluid to stand the same effects took place as before. The filtrate also had the property of coagulating animal albumen.

In order to investigate this subject more fully, the contents of the stomach were subjected to dialysis in a glass vessel prepared for the purpose by forming a diaphragm of parchment paper, and the dialyzer so made was suspended in a porcelain vessel containing a small quantity of distilled water and allowed to remain at rest for forty-eight hours. Then the dialyzed fluid was seen to present a strongly acid reaction. To ascertain whether this acidity was again due to lactic acid, a small quantity was added to an equal amount of fresh unboiled milk, when no effect was observed, but upon subjecting

it to heat the casein became entirely coagulated and in a few minutes was perfectly firm. To this fluid obtained by dialysis were now added a few drops of a solution of nitrate of silver, when a dense white precipitate was thrown down, which was only partly cleared upon the addition of nitric acid, showing that it was not entirely composed of the lactate of silver, but probably partly of the chloride of silver; but then this chloride could not have been formed from free hydrochloric acid, because the milk-test showed that none existed. It was probably made from some of the soluble chlorides, as of sodium, which are known to exist in the stomach. In fact, this man had probably taken some of this salt with his food at breakfast, and then this chloride had undergone dialysis as freely as the lactic acid. As these facts are strongly characteristic of lactic acid, it seems justifiable to conclude that free hydrochloric acid, as such, did not exist in this gastric juice, but that its acidity was due to the presence of free lactic acid.

To determine the presence of phosphates, the original filtrate was evaporated to dryness over a hot sand-bath, and the residue then completely charred; after all organic matters had been completely destroyed, the ash was dissolved in hydrochloric acid, and then carefully filtered. This clear filtrate that thus resulted was neutralized with ammonia, when a white precipitate, the phosphate of lime, was thrown down. The quantity of phosphate was very small. There was no evidence of the acid phosphate of lime.

The following deductions confirm entirely those obtained by Profs. F. G. Smith and Rogers, of the University, from the analysis of the gastric juice of Alexis St. Martin.

I. The gastric juice presents an acid reaction both before and after filtration and distillation.

II. The acidity in this instance was not due to the presence of hydrochloric acid.

III. Lactic acid did exist.

IV. Acid phosphate of lime showed no evidence of its presence.

V. Neutral phosphate did exist, and was held in solution by the lactic acid.

I would take this opportunity of expressing my thanks to Mr. George Hay, a member of the class, and a gentleman of great experience as an analytical chemist, under whose careful supervision these experiments were conducted.

PHYSIOLOGICAL LABORATORY OF THE UNIV. OF PENNA.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF R. Y. LEVIS, M.D.

Reported by Dr. JOHN B. ROBERTS.

FIXED DRESSINGS IN THE TREATMENT OF FRACTURES—THE COMBINATION OF GLUE AND OXIDE OF ZINC A NEW MATERIAL FOR FIXED DRESSINGS.

IN treating fractures it is often desirable to apply some form of dressing which will hold the parts in perfect apposition and yet allow the patient to be out of

bed, moving about the wards of the hospital, or even taking exercise in the open air. This is not a matter of much difficulty in fractures of the bones of the upper extremity, for then, after an ordinary wooden or pasteboard splint has been adjusted, the patient can walk about as freely as he chooses; but until within a few years a fracture of the leg was kept at rest by using a fracture-box, and the patient confined upon his back for five or six weeks.

Undoubtedly the greater frequency of ununited fractures and delayed union in the lower than in the upper extremity is to be attributed in part to keeping the limb long in a horizontal position, or even elevated above the rest of the body; for the natural position of the limb is dependent, and its blood-supply is necessarily interfered with when the patient occupies the supine position for a period of five or six weeks.

The necessity for a dressing to overcome this difficulty has long been recognized by surgeons, and accordingly the different forms of immovable apparatus for the treatment of fractures have been devised. As originally proposed by Seutin, it has been modified and much improved from time to time, until now perfection has perhaps been attained in a new material or composition devised by Dr. Levis and used for some time in the Pennsylvania Hospital.

It is necessary that judgment be exercised to determine when the fixed dressing shall be employed, for its premature use may occasion much harm. It is not desirable to encase a limb in the immovable apparatus until inflammation and swelling have subsided, because, by exerting undue pressure, it might readily induce gangrene of the limb. After the patient, however, has been kept at rest for a week or more, and after the tumefaction and inflammation consequent upon the injury have abated, it is proper in simple fractures to apply the fixed dressing, which, permitting the patient to rise from his bed and go about on crutches, lessens very much the weariness of protracted decubitus.

Many substances have been recommended to give the requisite stiffness to the dressing, some of which are desirable on account of cheapness, others because of the rapidity with which they harden; the great desideratum being to have an article which possesses both these essential characteristics. Starch, dextrine, silicate of sodium or potassium, gum arabic and chalk, plaster of Paris, glue, and paraffine have all been experimented with, and each has found its admirers.

The starch bandage is applied by carrying an ordinary roller, which has been wet, up the limb, previously wrapped in cotton wadding, as far as deemed necessary; boiled starch is then rubbed into the bandage, after which the roller is carried downwards to the extremity of the injured limb, and again saturated with starch. This manipulation is continued until several thicknesses have been applied, when pasteboard splints softened by boiling water and moulded to the inequalities of the surface are adjusted to the parts, and surrounded by another layer of starch bandage. In the course of twenty-four or thirty-six hours the starch becomes dry, and the dressing, strengthened by the interlying pasteboard, acts as a firm support to the fractured bones.

The silicate of potassium or of sodium may be used in the same manner; but, as it dries much more rapidly than starch, it can be applied upon many layers of bandage, and therefore acquires the requisite degree of firmness without pasteboard as an adjunct, which only serves to complicate the dressing.

When these dressings have become perfectly dry, they can, if it is thought necessary, be split up the middle of the leg by Seutin's scissors, and then retained in apposition, and their pressure regulated, by an additional bandage.

A very excellent fixed fracture-apparatus, denominated the Bavarian dressing from its extensive use in the late Franco-German war, is made with plaster of Paris in the following manner. Two pieces of flannel, each large enough to envelope the limb once, are selected and laid one upon the other; down the middle from one end to the other they are stitched together by two seams, say two lines apart, in order to form a hinge when the dressing is complete. The flannel is adjusted to the limb so that the seams lie along the posterior aspect; and then, while an assistant holds the *inner* layer close around the limb, the surgeon rubs upon it a sufficient quantity of plaster mixed with water. Before this becomes hardened the outer layer of flannel is also drawn up tightly around the limb, and thus, in a few moments, is made a case composed of two layers of flannel with plaster between them.

As soon as hard, the case is removed by opening it like a book, which can be done because the seams prevent the plaster getting between the layers posteriorly, and thus form a hinge; the edges of the flannel having been trimmed off smoothly, the apparatus is re-applied, and retained by a simple roller.

This form of dressing was much employed in the hospital a year ago; but although the limb is firmly encased, and the plaster rapidly desiccates, yet there are a number of objections to its use. In the first place, making the case is a dirty process; then the plaster sometimes becomes brittle and crumbles; but the greatest objection is the weight of the dressing, which renders it tiresome for the patient to walk about. From the rapidity with which it can be applied, the Bavarian dressing is particularly suited for military emergencies, when men having sustained fractures must be transported, but for civil practice it is too heavy for the patient to wear.

After experimenting with various kinds of fixed dressings, Dr. Levis seems to have arrived at one which fulfils all requirements; being cleanly in its application, drying with sufficient rapidity, removable without difficulty, exceedingly light, and withal very cheap. The fixing material is ordinary glue, with which oxide of zinc has been incorporated, either by the manufacturer or by the surgeon at the time of using it, in order to cause it to harden rapidly.

Several pieces of flannel—old blankets or worn-out underclothing answering the purpose admirably—are selected and cut the requisite size. One of these is laid around the limb, and the two edges are tightly stitched together along the anterior surface, allowing the edge to project above the seam; then the melted glue, with oxide of zinc, is painted upon this with a brush. The dressing may be strengthened by an additional layer of flannel or blanket saturated with the glue and oxide of zinc, and made to adhere to the underlying layer. A third or even a fourth layer may be thus applied, if it is deemed necessary, and the limb supported until the dressing dries, which requires from four to eight hours.

The stitches of the seam on the front of the limb having been cut with scissors, the edges of this elastic case are sprung apart, and the dressing removed. The edges are then trimmed smooth, and a number of eyelets inserted, in order that the case may be laced like a shoe, and the degree of pressure regulated.

This fixed fracture-apparatus is exceedingly light, is made from materials almost everywhere obtainable, and is much cheaper than the silicate dressing. There are at all times pieces of waste flannel or cloth about a large hospital which can be appropriated, while the glue and zinc could probably be supplied at a very low price per pound,—a quantity sufficient for the manufacture of many such splints. Another advantage is its elasticity, which permits its removal without endangering the splint, for it can be pulled apart, and immediately

springs into place around the limb to which it has been moulded.

By a little care and dexterity in stitching on the layers of flannel, the surgeon can readily shape the dressing so that both the leg and the foot are completely encased.

TRANSLATIONS.

THERAPEUTIC AND PHYSIOLOGICAL ACTION OF IPECACUANHA AND OF ITS ALKALOIDS.—Dr. Polichronie has made, in M. Vulpian's laboratory, a series of very interesting researches in order to ascertain the mode of action of ipecac and emetine. M. Polichronie's conclusions are as follows:

1. Emetine is the true active principle of ipecacuanha; all the physiological, therapeutic, and toxic properties possessed by this plant are due to the presence of its alkaloid.

2. In dysentery, as in diarrhœa, ipecac administered by injection possesses as active properties as when it is given by the mouth, according to the Brazilian method.

3. Ipecac by injection is one of the best forms of treatment which can be employed in cholera infantum; it may be supported for a long time without enfeebling young subjects.

4. In tuberculous diarrhœa, whatever may be the period, injections of ipecac give good results.

5. This medication may also be employed with advantage to combat the profuse sweats of phthisis.

6. Emetine is a highly toxic substance: it may give rise to death in animals in two ways,—sometimes by prostration of the nervous system, sometimes, when given in smaller doses, by the intense enteritis which it provokes.

7. Two hypotheses are possible to explain the favorable action of ipecac in diarrhœa: *a*, a vaso-constrictive action, which diminishes the abundance of the secretions; *b*, a substitutive action, which results from the inflammation of the mucous membrane.

8. The vaso-constrictive action does not take place, as experiments made upon the nerve of the submaxillary gland and upon the arterial tension show.

9. The production of inflammation of the gastro-intestinal mucous membrane, the duration of which is prolonged after vomiting has been brought about, seems, on the contrary, to plead in favor of the second view.

10. Emetine causes vomiting at the moment when it is eliminated by the gastric mucous membrane, while vomiting is retarded, and even more frequently does not take place after section of the par vagum. It is quite different with apomorphia and tartar emetic. These two substances bring about vomiting as quickly when these nerves are cut as when they are intact.

11. Finally, physiological and chemical researches upon the medicine argue in favor of elimination of emetine by the gastro-intestinal mucous membrane.

12. Emetine has no direct vomitive action upon the central nervous system, as is proved by direct injections of this substance into the cerebral arteries.

13. Therefore, it may be admitted that, in diarrhœa, emetine acts by substituting for the pathological inflammation a fresh one tending to spontaneous cure, its effect in these conditions being in every way comparable to that of purgatives or nitrate of silver.

14. In sweats we can no longer admit a vaso-motor action, and we are obliged to believe either that being eliminated by the sudoriferous glands it tends to restrain their secretion, or, better, that it acts by the revulsion which it causes to the digestive tube (Thèse de Paris, 1874).—*Bulletin Général de Thérap.*, January, 1875.

CHLOROSIS IN CHILDREN.—Dr. M. E. Bouchut recently delivered a clinical lecture on this subject at the Hôpital des Enfants Malades. The lecturer began by alluding to the fact that chlorosis as found in young girls is rare among children. Usually the chlorosis of children is rather a pseudo-chlorosis, due to some visceral affection. The two diseases are frequently confounded, but a distinction should be made between them, since we know that in true chlorosis we have a spontaneous insufficiency of blood-globules, or rather an insufficiency the causes of which are unknown to us. In pseudo-chlorosis, on the contrary, there are always lesions of a more or less appreciable kind, visceral affections evident or latent. It may occur after epistaxis, intestinal hemorrhage following enteritis, albuminous nephritis, chronic bronchitis, chronic amygdalitis. Any of the diseases of children may bring about this condition, of which physicians too often do not take proper account.

M. Bouchut then directed attention to certain cases in the hospital illustrative of the different forms of the affection. In the first of these, a child, he remarked that the cause of discoloration of the skin would be sought in vain; the chlorosis had come almost without symptoms. There had been no diarrhoea, no constipation, no catarrhal affection of the intestine, the vesicular murmur in the lungs was normal, the heart was decidedly dilated. No blowing, præcordial, aortic, or carotid murmur could be detected save by pressure over the latter. The child had merely general discoloration of all the cutaneous and internal teguments, at least so far as the latter were visible,—that is, of the mucous membrane of the mouth and lips. The nails also were decolorized. The first symptoms noticed had been headaches; she had not suffered from pain in the side or stomach; had not had syncope.

A second case in a child presented similar symptoms, with the addition of fainting-fits. A third case was of a somewhat different nature; it concerned a young girl fourteen and a half years of age. Her disease was the chlorosis of women. She menstruated regularly but scantily; the discharge was very slightly colored. She had had dysmenorrhœa and bleeding at the nose, but the latter was not sufficient to account for the disease.

As this girl had arrived at an age when moral causes might have given rise to the disorder, this point was inquired into, but with a negative result. Her hygienic surroundings had also been good. Two other cases occurring in girls of twelve and seven years respectively were also alluded to. No cause could be ascertained for the disease in either instance.

In these four cases, united by the symptom of globular insufficiency, the diagnosis was comparatively easy, but in other cases, remarked M. Bouchut, this might present considerable difficulty. Occasionally one sees children with neuralgias, malaises, with discoloration more particularly of the mucous membranes: in these cases one has under examination a doubtful case; chlorosis is diagnosed with an interrogation-point, and the neuralgias, etc., are called chlorotic.

The child might have a blowing murmur in the region of the heart: anæmic murmur, one says; but this blowing murmur may belong to an endocarditis, and in place of a true chlorosis one may have a pseudo-chlorosis.

M. Bouchut went on to say that he had long held to the idea of an anæmic, a chlorotic murmur; little by little, however, he had finally come to abandon this notion as false. Experiments made by M. Chauveau, of Lyons, had proved that intra-vascular murmurs depend neither upon the character nor upon the density of the liquid carried in the vessels, but are to be attributed entirely to mechanical causes, and are the result of vibrations. Blowing murmurs cannot, therefore, serve in the diagnosis of chlorosis.

Virchow has lately advanced the theory that chlorosis is not produced by an insufficiency of globules, but that it is always an anomaly of the system of vessels; narrowing of the aorta, for instance. There are then numerous blisters, a honey-combed condition of the middle coat of the arteries; then hypertrophies of the heart, dilatation, fatty degeneration of the heart; such, according to Virchow, are the causes of a chlorotic affection.

The objections to this theory, according to M. Bouchut, are, first, the rarity of post-mortem examinations in cases of chlorosis; second, the impossibility of thus explaining instantaneous chlorosis brought about by moral causes; and third, an objection which would seem to annul this theory of a vascular origin of the disease is its temporary nature and curability under the influence of iron or hydrotherapy within a few months.

In the face of the existing difficulties in diagnosis, and when there is an aortic murmur, the diagnosis is to be made differentially. Finding nothing else, to an insufficiency of the blood-globules is attributed the cause of the disease. Finally, as to treatment, stimulants may be employed as well as tonic preparations, iron in all forms,—iron by hydrogen, by electricity, pyrophosphate of iron, etc. These medicines should be given in small doses and frequently repeated. In some cases ferruginous mineral waters are beneficial. In general the soluble preparations, as lactate of iron, are undesirable, on account of their tendency to form tannate of iron with the astringent fluids of the mouth, and thus cause discoloration of the teeth. The patient's stomach should also be stimulated by aromatic wines, wine of gentian, etc. Hygienic means—fresh air, bathing in sea and river water, inhalations of compressed air and oxygen, with a course of hydrotherapy or at least of daily douches—will be found beneficial.—*Le Mouvement Médical*, Dec. 19, 1874. X.

THERAPEUTIC NOTES.

TO MAKE BRANDY.—Take 20 gallons proof spirits, 5 gallons pure cognac brandy, 1½ ounces oil of cognac, ¾ ounce œnanthic acid, ¾ ounce acetic ether, 1½ ounces tincture of kino, 1 pint simple syrup, mix, and color to suit with burnt sugar. If it is desired to imitate any other brandy, use that instead of the cognac. But this method of adulteration costs too much, as it requires pure brandy, and oil of cognac is rather expensive. The following will not cost so much.

To make cognac brandy, 20 gallons proof spirits, 2 ounces acetic ether, 2 ounces acetic acid, 2½ ounces tincture of kino, 5 pounds bruised raisins, 2 pints simple syrup, color with sugar, let it stand two or three weeks and draw off.—S. P. Sharples, in *Journal of Applied Chemistry*.

TREATMENT OF PRURITUS VULVÆ.—M. Hardy frequently employs the following formula:

R Hydrarg. chlor. corros., gr. xv;
Alcohol., ʒiii;
Aq. destillat., ʒiii ʒv.—M.

Tablespoonful in a tumblerful of warm water. Avoid rubbing the parts while applying the lotion.

In that form of pruritus vulvæ so often found accompanying pregnancy, Danyau employs the following formula:

R Zinci oxid., ʒi;
Sodii borat., ʒss;
Cerat. simpl., ʒss;
Ol. amygd. dulc., q. s.;
Morphiæ muriat., gr. iii.—M.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, FEBRUARY 13, 1875.

EDITORIAL.

HOPKINS UNIVERSITY.

MUCH as we may enjoy the deserved plaudits awarded of recent times to American surgery and American medicine, every honest American physician must recognize with regret that the *science* of medicine has not flourished on this continent; that the higher original work on which the art is founded comes almost solely to us from abroad. Recently, it is true, papers of real value upon physiology and the kindred sciences have straggled into the journals; but many an insignificant European town eclipses the great continent of America in the amount of value which it yields to the abstract medical sciences. This is not because the German intellect is superior to the American, nor even because it is "more scientific and less practical" than that of the American, but because a scientific career in this country is scarcely possible to any one who has not a private fortune at his command. It is commonly stated that the German is willing to live on less than is the American, and therefore devotes himself to science although it does not pay. There may be a certain amount of truth in this, but undoubtedly that amount is very limited. In selecting a career, a young man balances the prospects on either side. Practising medicine does not pay so well in Germany as with us, and consequently the opposition to the choice of a scientific career is less. More than this, in Germany science does pay, and does pay those well whose ability enables them to draw the prizes.

Von Recklinghausen recently refused, it is said, an offer of ten thousand dollars a year to go to Vienna. Where is the professorial position in the United States that pays five thousand dollars steadily? and ten thousand dollars in Germany is worth fifteen thousand here.

A purely scientific medical career is almost an impossible thing in America; and hence it is, as the *Nation* puts it in regard to other departments, that "to the higher thought of the world we contribute shamefully little." It is therefore with the most unbounded satisfaction that we see a prospect of a better day for our country in the Hopkins University. This institution, it will be remembered, was founded by the late Johns Hopkins, of Baltimore, who left \$3,500,000 for the endowment of the University, and a like sum for the foundation of a hospital in connection with it. Fortunately, the bequest was untrammelled, and the twelve trustees were well selected. They appear to be men of sufficient mind and culture to recognize the importance of using these great funds so as to build up a real seat of learning, not a mere high school dignified by the sobriquet of a university. What they have done may be judged by the following extract from a contemporary:

"They accordingly sent for President Gilman, of the California University, and asked him what he would do if he were put at the head of the new enterprise and were left perfectly free. He said in substance that he would make it the means of promoting scholarship of the first order, and this by only offering the kind of instruction to advance students which other universities offer in their post-graduate courses, and leaving the kind of work now done by under-graduates to be done elsewhere. For this purpose he would select as professors men now standing in the front rank in their own fields; he would pay them well enough to leave them at their ease as regards the commoner and coarser cares; would give them only students who were far enough advanced to keep them constantly stimulated to the highest point; and he would exact from them yearly proof of the diligent and fruitful cultivation of their specialties by compelling them to print somewhere the results of their researches.

"We are glad to say that the Hopkins trustees fell in cordially with Mr. Gilman's terms, and offered him the presidency of the new institution, and that he will probably accept it. It is a great opportunity, and we hope and believe it will be rightly used."

All this, to us, reads too much like a dream to be true. To see a really great medical school, every one of whose professors holds his position by virtue of the title-deeds he yearly produces,—a college which is in truth a great centre of medical thought, and not merely an elementary school of medicine,—

a place where the really great intellects which exist among us shall be freed from the necessity of fretting their lives away in the details of a practice which, perhaps, would be better attended to by inferior men,—a place which shall gather up that great waste of talent which eats up the higher life of our country,—to see this is more than we had ever hoped for. We can scarcely yet believe that no local reputation or influence, no “grandmothers or grandfathers,” will prevail, but that only such talent as has proved itself will be admitted to this institution. One thing is certain: by choosing the best men from all portions of the United States, giving living salaries, and urging to work, these twelve trustees can do more for American medical science than the American Medical Association has done during the whole of its highly honorable and most productive career.

MOST of our city readers are familiar with the shooting of Dr. Henry R. Wevill, an account of which was published in our columns some little time since. Dr. Wevill has been, of course, left a cripple for life, with his business broken up, and all his available funds spent during the long and severe illness which followed the amputation. It is proposed to raise a fund to enable him to prosecute the person who did the shooting. We commend this matter most heartily to members of the profession. Contributions may be sent to Dr. Thomas G. Morton, or to the editor of the *Philadelphia Medical Times*.

THE funeral reform seems to us to be nearly brought to a *reductio ad absurdum* in the number of the *Lancet* for January 16. Carrying still further the suggestion of Mr. Hodan in the *London Times*, that wicker-work coffins should be substituted for the nearly imperishable caskets now employed, our medical confrère suggests that all coffins shall be abolished, so as to save expense, and so that the ground can be readily tilled, declaring that “even the wicker-work coffins would present serious obstacles to tillage.”

ACCORDING to Dr. Cameron's report, twenty-one thousand pounds of unsound meat were condemned in Dublin during December last. We would like a report as to how many pounds of unsound meat were *eaten* in Philadelphia during the same period.

THE London Obstetrical Society, according to the *London Lancet*, by its almost unanimous decision that women are not admissible to its fellowship, expressed the feeling of a large majority of its members, that women by nature are disqualified from practising obstetrics.

LEADING ARTICLES.

THE USE OF COLD IN FEVER.

OF all recent improvements in medicine, no one appears to bear with it promise of so much practical life-saving value as does the use of cold in fever. The application of cold water is no new thing: employed by Galen, used not infrequently during the last century, first systematized and insisted upon by Currie, cold bathing in fever was brought before the world as a really new-born measure by Brandt of Stettin, and received the seal of permanent usefulness from the scientific clinical labors of Jurgensen at Kiel. In his article upon the subject, Jurgensen stated that from the year 1850 to 1861 there had been treated in the hospital at Kiel, according to the expectant method, three hundred and thirty typhoid-fever patients, with a mortality of fifteen and four-tenths per cent.; while from 1863 to 1866, during which period the anti-pyretic method was employed in one hundred and sixty cases, the mortality was three and one-tenth per cent.

Attracted by this remarkable statement, Liebermeister entered upon a very elaborate clinico-physiological research, and has been followed by a large number of observers. In this country the method is scarcely more than beginning to attract attention, and, so far as I know, no exhaustive résumé of the work accomplished has as yet appeared in the language, so that a series of leading articles upon the subject will probably not be lacking in interest.

The consideration of the method naturally divides itself into—first, a study of its physiological action; second, an investigation as to its clinical value; and third, a more particular account of its effect, the cases to which it is best adapted, and the method of its application.

It must be remembered that cold is not an entity, but is only a term employed for brevity's sake to express the abstraction of heat. The effect of the abstraction of caloric when the bodily temperature is above normal is in no wise dependent upon or parallel to the effect of a similar decrement of heat when the animal temperature is normal. It is therefore evident that no abstract discussion of the effects of cold upon the healthy organism is necessary to the right understanding of its therapeutic use; and I shall entirely remit the consideration of this to works on physiology and the practice of medicine.

On the other hand, a discussion of the effects of excessive temperature upon the human organism would be very pertinent to the matter in hand. The effects of acute pyrexia have, however, been so freely commented on in the columns of this journal that their consideration here is scarcely necessary.

The effects of a long-continued pyrexia, not sufficiently intense to induce immediate serious symptoms, upon the structure of the various tissues, have been elaborately investigated by Liebermeister (*Deutsches Arch. für Klin. Med.*, Bd. i.), who found that the liver, spleen,

kidneys, voluntary and involuntary muscles, blood-vessels, and even the nerve-centres undergo a granular degeneration during a continued pyrexia. The lesion was constantly present in the bodies of those who had suffered in this way during life, entirely independent of the nature of the primary disease. In cases of infectious fever in which the temperature had never been high, this granular degeneration did not exist. Previous to the investigation of Liebermeister, Zenker had demonstrated that the muscles undergo a peculiar granular degeneration in typhoid and other fevers, and the fact has been abundantly attested by later observers. I do not know that the observations of Liebermeister as to the occurrence of this lesion in non-infectious pyrexia have been confirmed, but I have no doubt of their correctness.

It is evident from the above brief résumé that in fever a primary therapeutic indication is to reduce the temperature. Of course, if possible, this should be done by checking the excessive production of heat; but, unfortunately, this often lies out of our power, and we are forced to abstract the heat by mechanical means.

It is *a priori* impossible to determine what effect upon the production of heat the rapid abstraction of it would have, but, from the well-known powers of the organism to resist external cold, it would seem probable that the heat-production would be increased rather than diminished by the abstraction of caloric. An experimental study of this problem has been made by several observers.

Weisflog (*Deutsches Archiv für Klin. Med.*, Bd. ii. p. 570) has found that the local abstraction of heat by a cold sitz-bath causes a rise in the temperature of the axilla, and that in fever-patients, unless the sitz-bath is prolonged over twenty minutes, no fall of the bodily temperature results.

In 1860, Kernig (*Reichert's Archiv*, 1860) found that a healthy man in a bath of the temperature 28°–30° C. produces about twice as much heat as normal; in baths of 24°, about three times as much; and in baths of 20° C., about four times as much.

Liebermeister found that in a healthy man exposure to cold ("Beobachtungen und Versuche über die Anwendung des kalten Wassers bei fieberhaften Krankheiten," Leipzig, 1868) for a brief period of time causes a rise in the bodily temperature, and on extending his researches into fever proved that where the external cooling was not too powerful or too long continued the same was true of fever-patients. From this it follows that the use of external cold stimulates heat-production. This has been confirmed by the chemical researches upon men of J. Gildemeister (*Virchow's Archiv*, Bd. lii. p. 131) and of Prof. Liebermeister (*Deutsches Archiv für Klin. Med.*, Bd. x. p. 89), and by those of A. Roehrig and N. Zuntz (*Pflüger's Archiv*, Bd. iv. p. 66) upon animals, which show that both in health and in fever very much more carbonic acid than normal is eliminated under exposure to cold. Cold baths, therefore, do not have a direct immediate tendency to diminish the production of animal heat, but, on the

contrary, increase it. The further investigations of Liebermeister (*loc. cit.*, p. 134) and others have shown, however, that the first rise of temperature produced alike in healthy and in fever subjects by exposure to a moderate and not too long continued cold is followed after removal of the cold by a fall of bodily temperature of greater or less degree. Whilst, therefore, external cold first stimulates, it afterwards depresses the production of animal heat.

The further experiments of Liebermeister (*Deutsches Archiv*, Bd. x. p. 425) upon the elimination of carbonic acid are also in accord with his temperature-study, for he found that after the bath the elimination sank down below normal, and continued so for some considerable time.

The results of the physiological study of the effects of cold in fever may be summed up as follows:

During a prolonged, and severe application of cold the bodily temperature falls, although an increased production of heat—*i.e.*, consumption of tissue—occurs; afterwards, the bodily heat continues to fall, or but slowly regains its former position, because there is a diminished production of animal heat. In most cases of fever the increased consumption of tissue which occurs during the cold bath is of no moment; in the hectic of phthisis it may be of importance.

The above considerations comprise the most important part of our physiological knowledge upon the subject in hand; in the next article the clinical evidence as to the value of cold bathing will be considered.

H. C. W.

CORRESPONDENCE.

BALTIMORE, January 30, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—At a meeting of the Medical and Surgical Society, Prof. Arnold related the case of a young man, now in the Washington University Hospital, who takes from ten to twelve grains of morphia daily. He fell from a trapeze, on which he was performing, and injured his spine. He suffers intense pain, and life is miserable without morphia. He would like to abandon its use, but cannot find a substitute which will make the pain endurable. His health does not seem at all impaired by the opiate. De Quincey and Coleridge lived to a good old age, and it would seem that opium of itself does not have such a deleterious effect on the digestive system as we have been led to believe. Dr. Wilkins said that he knew a lady who uses sixty to ninety grains of morphia daily. There is no impairment of digestion.

Dr. Uhler referred to two cases of belladonna-poisoning. In one he used stimulants, in the other opium. The results were equally good.

At this point quite a spicy discussion arose upon the supposed antagonism of belladonna and opium, and the reliability of therapeutics. The general opinion was that no true antagonism exists between the two

drugs mentioned. In regard to therapeutics, the assertion was made that it was so unreliable that it was difficult to base any opinion upon it, and that it did not become any one to dogmatize in the matter; that any dunce can prescribe, but that it requires education to diagnose and apply proper remedies to the existing condition of the patient.

At the Baltimore Medical Association, the President, Dr. Tanneyhill, related the case of a lady who had aborted eleven times from syphilitic contamination. Potassium iod. and hydrarg. bichlor. had been used, and under their influence the child had approached nearer to a healthy condition than in any previous pregnancy; but in none was the child viable. He thought that there was hope that eventually she would bring forth a living child.

Dr. Atkinson said that in long-standing cases of syphilis the tendency is to relapse, and that it is necessary to keep up the treatment for a long time.

Dr. Tanneyhill said that in this case he had treated it continuously for nine months.

Dr. Hoel said that a gentleman who had suffered from syphilis years ago, consulted him in regard to the propriety of marrying, which he discountenanced. Another physician, however, informed him that there would be no danger, and he married a healthy widow. She aborted at six months. In her second pregnancy she exhibited nodes on the tibia, and syphilitic disease of the nose. The child was withered, and was unable to nurse. It was kept alive by brandy, and, after it had gained a little strength, was put to a wet nurse, and did well. The parents were placed upon anti-syphilitic treatment, and, eighteen months after, the mother was delivered of a perfectly healthy child. For seven months there were no signs of syphilis, and the treatment was discontinued. He was called one night to see her, suffering from what was supposed to be cholera morbus, but which proved to be gastritis. She was getting along well, when paralytic symptoms appeared, and she died in a very short time. He thought this paralysis due to syphilitic disease of the nervous system, especially as she had complained for some time of a dull boring pain in the side of the head.

The Medical and Surgical Society held its annual election on the 7th instant. The officers for the year are—President, Dr. J. W. P. Bates; Vice-Presidents, Drs. C. M. Morfit and J. R. Uhler; Recording Secretary, Dr. G. L. Wilkins; Corresponding Secretary, Dr. J. H. Rehberger; Treasurer, Dr. P. Dausche; Committee of Honor, Drs. Morris, Monmonier, and Reynolds; Executive Committee, Drs. Cathell, Evans, and Dodge; Committee on Lectures and Discussions, Drs. Winternitz, Caldwell, and Rutledge; Librarian, Dr. E. F. Hamel. After the election, the Society was invited to partake of a fine supper provided by the retiring President, Dr. Morris. The session was quite prolonged, and was enjoyed by all.

The Maryland Academy of Science formally opened their new hall last week, with an oration by Prof. E. Lloyd Howard, M.D. After much hard labor and

many disappointments, the Academy, from a very weak organization, has developed into a strong and earnest scientific body. It contains the names of many prominent physicians on its roll, and they add much to the interest of its semi-monthly meetings. Its collection is large, well displayed, and constantly increasing. Prof. Philip R. Uhler, the Librarian of the Peabody Institute, is the President.

MEDICUS.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

At a conversational meeting held Wednesday, December 9, 1874,

Vice-President Dr. I. S. ESHLEMAN in the chair,

Prof. HENRY H. SMITH presented to the Society a patient suffering from a very bad *ununited fracture of the shaft of the femur*.

Before showing the limb, Dr. Smith requested the gentleman to walk the length of the hall, which he did with only a slight limp.

Dr. Smith then read the following history of the case.

"Colonel J. W. T., of Iowa, æt. 56 years, was thrown from his wagon on the 20th of May, 1873, and his right femur broken, so as to make a comminuted fracture that separated the entire middle third of the femur from its superior and inferior thirds. After being dressed for nine weeks with a straight splint, he was permitted to sit up, the splint being removed. It was then discovered that, whilst there was partial union of the upper and middle thirds, there was no union at the junction of the middle and lower thirds of the bone. Upon consultation, about the eleventh week after the injury, it was decided to place a *seton* between the ends of the bones at the lower seat of fracture. This being left in place for eight days developed such active suppuration under the femoral fascia, with high inflammatory fever, as to threaten the patient's life, and the seton was therefore withdrawn. Ten days subsequently, when the general symptoms had improved, the fracture was again permanently dressed with the same straight splint, and the patient kept at perfect rest, on his back, for eight weeks. On again examining the limb, twenty weeks after the accident, no union had been obtained, and, as his general health and strength were much impaired by suffering and confinement, it was decided to put him on crutches and let him take exercise as he could.

"After three months' trial, the failure of union rendered the limb a useless encumbrance. At this time he was advised by his physician to go to Chicago and obtain one of Dr. Smith's artificial limbs for ununited fracture, as represented in his 'Surgery.'

"This apparatus, though imperfectly made and fitted, enabled him to obtain some use of the limb, so that, by the aid of crutches, he was able to travel to Philadelphia, where he has been fitted by Spellerberg & Gemrig with two limbs, to insure him against injury to either one."

His ability to walk well with the artificial limb was thoroughly recognized by the Society. The apparatus being removed, the members examined the limb freely and found as follows:

Present condition, December 9, 1874.—The fracture is very apparent, and the union of the lower and middle thirds of the femur so imperfect as to permit the leg to be bent to a right angle with the middle of the thigh; the leg and foot to be rotated so that the calf and heel

would be uppermost whilst the patient lies on his back, whilst the end of each fragment is closed at its medullary canal and solidly rounded off. Extension separated these ends about one and a half inches. The upper and middle thirds at the seat of fracture presented a true false-joint, the ligamentous union of which gave more firmness to this fracture, but it was unable to sustain the limb. The entire thigh was much emaciated, the muscles atrophied, and the course of the seton between the ends of the lower fracture was readily seen.

Dr. Smith said he had especially wished the members of the Society to see how well this patient could walk with the apparatus on, though his limb was otherwise useless, because he had for a long time taught and shown that amputation for an ununited fracture was an unjustifiable operation, a patient walking better with his limb on in one of Dr. Smith's forms of splint than he could with his limb off in the best artificial limb ever made. There was also the constant chance of union being obtained through the apparatus, by the principle proposed by Dr. Smith,—viz., pressure and motion at the seat of fracture.

Dr. Smith also stated, in reply to an inquiry by Dr. Lee, that he had published a full account of the forms of his apparatus, principles of treatment, etc., as required in the treatment of ununited fracture, in his work on Surgery, and also in the *American Journal of the Medical Sciences*, vol. xxix., new series, 1855, and had given drawings of the apparatus, which were also published in most of the catalogues of the cutlers in the United States; but, as his paper appeared to be unknown to many of the members of the Society, Dr. Smith proposed referring to the subject of this treatment on some future occasion.

The apparatus, he stated, was applicable to every form of false-joint in any of the extremities, as the fore-arm, etc.

Dr. O'HARA asked the experience of the gentlemen present on scarlatina as at present occurring.

Dr. HAMILTON said, in reply to a question by the President in regard to the prevalence of scarlet fever, that he had not seen many cases lately; that the returns of the Board of Health, the only reliable source of information, showed a slight increase for the few past weeks. In this connection, Dr. H. stated that in one family he had recently seen four children affected with, apparently, a combination of diphtheria and scarlet fever. Two of the cases were very mild, the third not severe, the fourth violent and peculiar in some features. No rash appeared in any instance. The attendance upon the fourth case, a boy of eight years, whose throat was ulcerated and nasal passages discharged an excessive amount of fetid purulent fluid, had ceased, but was, at the end of five days, resumed. The face and feet were then œdematous. Two days later, the right side of the chest gave no normal sound; left side perfectly resonant. In three or four days the resonance had returned, almost completely, to the right side, and had disappeared from the left, to return almost as quickly as in the case of the right side. An examination of the chest was made during convalescence, by Dr. William Pepper. The special feature of this case is of course seen in the rapidity of effusion and absorption of serous fluid.

Dr. H. C. WOOD, Jr., then delivered a lecture on the principles which govern the use of electricity in paralysis. Dr. BALDWIN asked Dr. Wood how soon after the occurrence of an attack of hemiplegia he would consider it safe to commence the use of electricity.

Dr. WOOD answered, usually not for two months; the use to be continued until the muscles had recovered their normal tone.

Dr. BARR said that Bard and Rockwell, in their "Medical and Surgical Electricity," mention the case

of a dog, whose skull had been trepanned, in which the ascending current caused the vessels to contract and the brain to fade perceptibly, while the descending current caused the vessels to fill and the brain to protrude through the opening in the cranial vault. He also asked how Dr. Wood accounted for the fact, if such it be, that one pole of the faradic current gives more pain to the hand than the other.

Dr. WOOD replied that usually it was very difficult to distinguish between the poles of a secondary current. He had always seen those who said they could do it fail when the electrodes were applied to the arm. Undoubtedly, however, one of the to-and-fro currents is stronger than the other.

Dr. COLLINS thought the same effect was produced by both poles when the pressure and moisture were the same.

GLEANINGS FROM OUR EXCHANGES.

SPERMATIC COLIC.—Reliquet insists much on these facts in making the diagnosis: 1, that the first pain is produced suddenly at the time of coitus; 2, that subsequently every erection, or even every desire for coitus, produces pain. They are, he says, the subjective symptoms. These, combined with the objective signs, especially with the uniform swelling of the seminal vesicle, should lead to a correct diagnosis.

He reports the case of a man, æt. 35, who for several years had often suffered, when at stool, from the emission of a small quantity of thick, white liquid. For two months he had experienced pain, extending from the anus to the perineum, or emissions, during coitus or when emptying the bowels. The erect posture and walking provoked frequent micturition. Attempts to retain his urine caused acute pain and cold sweats. The pain lasted four or five minutes after urination. He lost desire to sleep. Venereal desires and erection provoked pain. During one month and a half he had passed small quantities of blood with his urine.

A gum-elastic bougie was passed easily into the bladder, but caused excessive pain in the deep part of the urethra. He was sounded for stone the next day, but no foreign body was discovered in the bladder. On examination from the rectum, the left vesicula seminalis was found swollen, hard and smooth. It was painful on pressure. After the sounding, an attempt was made to pass the bougie once more, but the instrument was arrested at the neck of the bulb, and then withdrawn. After two or three minutes of extremely sharp, cutting pains in the penis and the anus, the patient stooped down, and, emptying the bladder, expelled as many as forty small opaque white bodies, about the size of a small pin's head or a lentil. They presented facets and blunt angles, like prostatic calculi, but their consistence was soft, and they could be crushed between the fingers. To the naked eye they appeared to be formed of a white homogeneous material, devoid of any capsule.

After the passage of these bodies, the symptoms quickly subsided, and, on examining from the rectum on the third day, the left seminal vesicle was found of the same size as the right.

The bodies were found to correspond closely to the concretions found in normal vesiculæ, only greatly increased in volume.—*Atlanta Medical and Surgical Journal*, December, 1874.

OPTIC NEURITIS (*The Lancet*, Jan. 16, 1875).—Dr. Hughlings Jackson insists (1) that severe neuritis may exist when the patient's sight is apparently perfect, and (2) that neuritis may (with large doses of iodide of potassium) pass away, leaving sight quite good.

FORCE AND STIMULANTS.—*The Lancet* of Dec. 12, 1874, asserts editorially that at the present day our treatment has assumed a character too decidedly stimulant and not quite sufficiently nutritive. Stimulants ought to be regarded as auxiliaries to nutrition more than they are at present. Nutritive material, as milk, meat-juice, eggs, and various forms of starch, ought to form a greater matter in the dietary of the sick than stimulants, whether nitrogenized or alcoholic; such materials, when assimilated, give supplies of force. Stimulants may assist in their assimilation, and do so; but in themselves stimulants only furnish limited supplies of force-bearing material. They are, however, a means by which the system may reach some of its physiological reserve fund. Such use may be advantageous or pernicious, according to circumstances; and an ill-regulated or excessive process of stimulation may give results as disastrous as a wise and intelligent resort to stimulants may be beneficial and preservative in its consequences.

TREATMENT OF SYPHILIS (*The British Medical Journal*, Dec. 12, 1874).—Mr. James R. Lane thinks that in the treatment of syphilis the main principle to be followed is, that mercury is the remedy for the secondary stage, and that the iodides are the remedy for the tertiary. He believes iodine to be seldom if ever useful, and usually harmful in the first, while mercury is rarely if ever admissible in the latter. There are cases, however, in which the two conditions overlap, in which tertiaries become developed while chronic secondary affections still remain; and here a combination or alternation of the two remedies becomes useful; alternation being better than combination, the iodide being used first until the tertiary symptoms are removed or amended and the health improved; after which a mild course of mercury may be cautiously resorted to for the remaining secondary affections.

ANEURISM (*The Lancet*, January 16, 1875).—Mr. C. F. Maunder believes that the result of the inquiries which Mr. Holmes has made will alter the views hitherto held by surgeons, as it appears that the mortality from ligature after compression has failed is ten per cent. greater than when the Hunterian operation has been performed at once, while others were not cured. Allowing for accidental circumstances, the results of the two methods, compression and ligature, have been as nearly identical as possible in a long series of cases extending over many years and a large variety of districts. Prolonged, gradual, and intermittent compression may either retain the aneurism *in statu quo*, or favor ill success altogether; but it must also be borne in mind that rapid compression is sometimes followed either by a return of the disease or by suppuration and sloughing of the sac. Of one hundred and six cases in which compression was tried, it was necessary to resort to the ligature in fifty-six; forty-seven recovered, and nine died.

The mode of treatment which Mr. Maunder advocates for the cure of popliteal aneurism, and all other suitable cases, is moderate compression, alternating with relaxation, say for a fortnight, with a view partly, if thought desirable, of promoting a more free collateral circulation in the limb; and, at the expiration of this time, continuous compression, either digital or instrumental (completely obstructing the artery), maintained under chloroform or opium, if necessary, for a period of from six to twelve hours, or even longer, and assisted by a tourniquet on the distal side of the sac if the first attempt does not succeed. Should a few sittings fail to effect good progress in the aneurism, the ligature must be resorted to.

After a review of his experience, he comes to the following conclusions:

1. That no case of aneurism is to be regarded as necessarily incurable.
2. That some cases of internal aneurism are apparently cured by absolute and prolonged rest, restricted diet, and other medical treatment.
3. That, when possible, compression, either proximal or distal, is to be employed in addition.
4. That in all aneurisms in which treatment by ligature is known to be a very fatal operation, the above rules are to be first applied.
5. That the treatment of progressive aneurism at the root of the neck by the distal operation is justifiable after medical treatment has failed.
6. That in rare instances only may an aneurism be treated by ligature before compression has been tried and has failed.
7. That digital is to be preferred to instrumental compression.
8. That chloroform and morphia are valuable aids to compression.
9. That chloroform will probably prove to be a more effectual agent than morphia in all cases, but more hazardous.
10. That the value of morphia should be more thoroughly tested.

EPILEPTIC DREAMS (*The Lancet*, January 16, 1875).—In chronic conditions of mental impairment it seems certain that "subjective" sensations are factors in producing delusions. Thus, a lunatic who has subjective smells may think his food is poisoned (compare the popular theory of the development of dreams, etc.). The temporary subjective sensations which usher in an attack of epilepsy probably give a turn to the mental disorder at the onset of and after the paroxysm. The probability is that such subjective sensations, which are practically external, develop or give a turn to dream-like states preceding complete loss of consciousness, or to the delirium or mania sometimes following the paroxysm.

EFFECT ON RESPIRATION OF THE CONDITION OF THE RESPIRATORY CENTRE (*The British Medical Journal*, January 2, 1875).—In a recent lecture on the Experimental Investigation of the Action of Medicines, Dr. T. Lauder Brunton alluded to the condition which is called "apnoea" by the German writers, in which the blood circulating in the respiratory centre is not at all venous, but is perfectly arterialized; the centre is less sensitive, the natural irritant—carbonic acid—is diminished or removed, and the respiratory movements cease. He continued as follows:

The activity of the respiratory movements and the amount of air respired in a given time depend on the degree of excitement of the respiratory centre. As we have just seen, this excitement depends on two factors: 1, the excitability of the centre; and, 2, the amount of irritation applied to it. In general, the venosity of the blood determines both factors, and it is not the venosity of the blood in the general circulation which does this, but only of that blood which courses through the vessels of the medulla. This was shown by Hering, who passed a stream of arterialized blood through the vessels of the head while venous blood was circulating in those of the body. The respiratory movements then ceased exactly in the same way as if the whole blood in the body had been perfectly oxygenated. When he reversed these conditions, and passed arterialized blood through the body and venous blood through the head, asphyxial convulsions took place. This shows that the degree of activity of the respiratory centre in the medulla oblongata depends on the greater or less venosity of the blood circulating through it, and not on an irritating action exerted by venous blood on the ends of afferent nerves in the lungs or other viscera.

The excitability of the respiratory centre may be greatly modified: 1, by the temperature of blood in it; 2, by the action of drugs upon it. When the blood becomes warmer, the excitability of the respiratory centre is greatly increased; the movements of respiration become much more vigorous, and it is no longer possible, by the most active artificial respiration, to produce a state of apnœa. Certain drugs, as tartar emetic, or apomorphia, when injected into the veins, also prevent the production of apnœa; but whether they do so by increasing the excitability of the centre, or by acting as irritants to it, is uncertain.

Other drugs, such as chloral, greatly diminish the excitability of the respiratory centre, so that the respirations become fewer, notwithstanding the increase of carbonic acid in the blood to which their diminution gives rise, and if the dose be large they may stop altogether. Apnœa may also be produced by means of artificial respiration with great ease after their administration, and it may last so long that one is sometimes inclined to think that the animal is not going to breathe again at all.

STRANGULATED HERNIA SUCCESSFULLY TREATED BY PNEUMATIC ASPIRATOR.—An engine-driver, aged 50, had suffered for three months from inguino-scrotal hernia. When first seen, the tumor in the scrotum was found to be tender on pressure, the patient suffering intense pain, and harassed with frequent vomiting, flatulence, and general uneasiness. All efforts at reduction failed. The attempts to restore the intestine by means of taxis were renewed the following morning, the patient being put under the influence of chloroform, but the results were still negative. A No. 2 needle (Dieulafoy's) was accordingly thrust at right angles to and well into the sac; on turning the tap, about two drachms of a serous fluid and bubbles of gaseous matter were drawn into the instrument, proving that the bowel had been perforated. The aspirator was emptied, and again set, and the needle drawn somewhat outwards. This change of position evidently placed the point in the hernial sac, out of which were drawn from four to five ounces of sero-sanguineous fluid. The tumor suddenly collapsed, and, on manipulation, the hernial protrusion was found to have disappeared. The patient made a rapid recovery.—*Edinburgh Medical Journal*, December, 1874.

CATALEPSY FOLLOWED BY EPILEPSY (*The Lancet*, January 9, 1875).—Surgeon-Major Chapple reports the case of an officer, æt. 30, steady and abstemious in his habits, quick and intelligent intellectually, whom he was asked to visit in consequence of sudden illness. He found him sitting at a table, immovable, pale, cold, with a weak pulse, and entirely speechless. On removing him to bed, he remained in any position in which he was placed. Soon after his head rested on the pillow, startling sounds became audible, creaking and straining so intense that it seemed as if the bones must break if the noise came from muscular action. Up to this time the body had been placid and still as death, but a severe epileptic fit then occurred, with the usual convulsions, after which he regained his health.

Subsequently he had attacks of petit mal, sometimes three and four a day, but the grand mal did not occur oftener than three times a year. Bromide of potassium was of great benefit to him.

PERIOSTEAL FLAPS IN AMPUTATION (*Chicago Medical Times*, January, 1875).—Tizzoni believes that the results of numerous operations on animals, and occasional examinations of stumps of patients, justify him in making the following statements as to the advantage of periosteal flaps:

1. The operation is easily performed. At the present

day, when pain and blood are spared the patient, it is a matter of small consequence if a little more time is consumed than usual.

2. The periosteal flaps retract considerably, but equally and without wrinkles.

3. These flaps will remain spread over the cut surface of the bone.

4. In twenty-four hours there will be a firm adhesion between the medulla and the flaps. Later, they consolidate with the bone. This early adhesion is of the greatest practical significance. It protects the medulla from the influence of the pus that may possibly form about the end of the bone.

THE SLEEPING SICKNESS OF WESTERN AFRICA (*The British Medical Journal*, January 2, 1875).—Surgeon-Major Gore gives a history and description of African lethargy, the treatment of which has proven so unsatisfactory, and the mortality so great,—seventy-three per cent. of those attacked having died. The first intimation is a swelling of the glands about or around the neck, accompanied by a gradual inclination to sleep, which increases; and the person so affected will fall asleep at all times, and in all places, no matter what he may be doing,—working, eating, walking, talking, or anything else,—only awakening at short intervals. Sometimes the body swells in the progress of the disease, and at other times in its first stage. The skin becomes dry and dusty, the strength palpably decays, and the most massive form becomes reduced. This continues for six or twelve months, more or less. Just before death, the patient suddenly ceases to sleep; this is the forerunner of death always.

GASTRO-PULMONARY FISTULA.—Fistulous openings between the stomach and other organs are, it is well known, the occasional consequence of the progress of gastric ulcers. Perforation of the diaphragm is one of the rarest of these events, and very few instances of it are upon record. A well-marked case, however, is described by Dr. Juliusburger, of Breslau, in the *Berliner Klinische Wochenschrift*, and is of especial interest from the marked symptoms which existed during life and rendered the diagnosis of the condition tolerably easy. Symptoms of gastric ulcer had existed for some months, when signs of perforation showed themselves, with peritonitis, etc., followed by fulness of the right side of the epigastric region, and in a day or two by dulness in the right side of the thorax. A month afterwards, after a rigor, quantities of stinking fluid were coughed up; the epigastric swelling, before dull, became resonant, and pressure upon it increased the expectoration, in which from time to time particles of food were found. Death occurred two months afterwards, and an ulcer was found on the posterior surface of the stomach, near the pylorus, which communicated by a small opening with a cavity the size of a fist, formed apparently by peritoneal adhesions, and containing air and fluid. At the upper part of this, a small opening through the diaphragm, about the size of a fourpenny-piece, communicated with the right lung, the openings of several small bronchial tubes being exposed. In both lungs there was disseminated tubercle, and in the spleen were some pyæmic abscesses.—*The Lancet*, January 16, 1875.

TREATMENT OF TYPHOID FEVER BY COLD (*The Practitioner*, January, 1875).—Dr. Frederick T. Roberts objects to a routine hydropathic treatment of any fever, but thinks it highly desirable that the members of the medical profession should be more generally impressed than they are at present with the usefulness of the various modes of applying cold to the surface of the body in febrile cases under certain circumstances.

He believes that the cases in which the more severe

methods of applying cold are indicated are those in which the temperature is already very high, and remains so, or shows a tendency to rise rapidly, especially if at the same time there are signs of much nervous disturbance. Unquestionably, this plan of treatment is not resorted to under these circumstances nearly so frequently as it ought to be. It is difficult to lay down any exact rule as to what temperature indicates the necessity for adopting it, but if it reaches to 106° Fahr., and shows no tendency to fall, or, still more, if it continues to rise, this treatment deserves due consideration. Necessarily, much will depend on the actual condition of the patient, and every case must be thoroughly considered in all its features. The best method seems to be decidedly that of placing the patient in a tepid bath and gradually cooling it. Affusion over the head is useful if there are marked nervous symptoms.

TREATMENT OF THE DIARRHŒA OF TYPHOID FEVER (*The Practitioner*, January, 1875).—Dr. George Johnson, after an experience of many years, has arrived at the conclusion that in the treatment of typhoid fever careful nursing and feeding are of primary importance, while, as a rule, no medicines of any kind are required, and, when not required, they are often worse than useless. The patients are fed mainly with milk, with the addition of beef-tea and two raw eggs in the twenty-four hours, and he gives wine or brandy in quantities varying according to the urgency of the symptoms of exhaustion, especially in the advanced stages of the disease. Milk should be given alone, unless the patient is able to digest eggs and beef-tea, and is one of the best antidotes for the diarrhœa of typhoid fever.

SYPHILITIC HÆMOPTYSIS (*The Lancet*, January 16, 1875).—At a recent meeting of the Clinical Society of London, Dr. Farquharson related a case of hæmoptysis occurring in a syphilitic patient, with no abnormal physical signs in the heart or lungs, and rapidly cured by iodide of potassium and perchloride of mercury. He believed the disease was due to an exudation analogous to that in condylomata, occurring in the minuter bronchial tubes, from which blood is slowly poured out into the air-vesicles, and, accumulating there, sets up irritation and gives rise to the hard cough. Hence the danger that destructive changes might take place in the lung-tissue if the exudation remained unabsorbed, and the value of anti-syphilitic treatment as compared with astringents.

Dr. Southey observed that such cases of hæmoptysis were not rare in syphilis, and that violent hæmoptysis was often the first symptom of disease of the lungs in syphilis. In these cases he had observed that the blood was dark-colored, and not bright red, as in phthisis; and there might be no physical signs in the lungs except the loss of breath-sounds over parts of the lung. He thought it probable that the exudation might be in the air-vesicles, and not in the small bronchi, in many cases, and the pathological condition giving rise to it was probably thrombosis of the pulmonary veins. Thrombosis is known to occur not infrequently in syphilis in the systemic veins; and this explanation would account for the absence of physical signs.

THERAPEUTICS OF IODIDE OF POTASSIUM (*The British Medical Journal*, January 2, 1875).—Mr. J. M. Wilson used iodide of potassium, in four-grain doses, every three or four hours, in a case of asthma. In a short time the asthma was relieved, but the patient was seized with intense pains across the loins, diminution in the secretion of urine, and great pain on passing it. This condition was relieved by appropriate treatment, and for a fortnight no medicine was given. Then the asthma returned, and the iodide was given again, and

was followed in a few hours by threatenings of the same pain and discomfort. The case was one in which there was a strong rheumatic diathesis, and the trouble following the administration of the iodide probably resulted from its having caused an increase in the amount of uric acid to be secreted by the kidneys. Dr. James Laird believes that the one distinct and indisputable action of the iodide of potassium is that of *stimulating the mucous membranes* and promoting their secretion. He explains in this way its beneficial effect in chronic winter cough, in asthma, in chronic bronchitis, in diphtheria, etc. He believes also that in all the various manifestations of struma, where the medicine is of service, it acts, so far as the iodine is concerned, in stimulating the mucous membrane of the stomach and duodenum—possibly by sympathetic action the liver and pancreas also—to increased secretion, whilst its alkaline base tends to promote the digestion of fat and starch. In such diseases as diphtheria, the object should be to produce its influence as rapidly as possible, whilst in others, as struma, small doses long continued are preferable.

UNILATERAL PARALYSIS OF THE PALATE (*The Lancet*, January 16, 1875).—In some recent remarks, Dr. Hughlings Jackson said that he had not discovered paralysis of the palate in uncomplicated disease of the portio dura nerve, and that deviation of the palate is not uncommon in healthy people.

This statement may seem a rash one, as paralysis of the palate is said by physicians of the greatest eminence to occur with facial palsy, owing to disease of the trunk of the portio dura nerve above the giving off of a branch to Meckel's ganglion, which branch, through the intermediation of that ganglion, is believed by most anatomists to supply the levator palati. According to Troeltsch, however, the levator palati is supplied by the vagus nerve. This would accord with the results of Dr. Jackson's clinical observation, as he has found well-marked palsy of one side of the palate, along with palsy of the vocal cord on the same side, from intracranial disease.

TREATMENT OF HYDRARTHROSIS.—In cases of dropsy of the joints, especially that of the knee, Dr. Bergeret finds the continued application of bags of hot sand to answer better than any other kind of treatment. When the acute stage is passed, and whatever may be the cause of the dropsy, he wraps the joint in a thick layer of cotton-wool, and applies to this a sac containing two or three litres of fine and very hot sand. The dropsy disappears in a few days. The sand must be very hot, and the heat may be kept up by means of covering with a blanket. The sand must not be too thick in the bag, so that it may extend easily on the knee, and overhang the hydrarthrosis in every direction.—*Journal de Thérapeutique*.

THE DIAGNOSIS OF FATTY DEGENERATION OF THE HEART IN ADVANCED LIFE (*The Lancet*, January 9, 1875).—Dr. Leonard H. Jayne, after seeing a number of fatal cases of fatty degeneration of the heart, believes that certain symptoms are diagnostic of that disease,—viz., feeble and irregular or intermittent pulse, dyspeptic symptoms, epigastric pain, frequent vomiting (more especially after taking food), and diarrhœa. In cases of simple hypertrophy, where there was no fatty degeneration present, he has never observed such symptoms as vomiting, gastric pain, diarrhœa, and feeble and irregular pulse.

SATURNINE GOUT (*The British Medical Journal*, January 2, 1875).—Dr. Wilks reports a case in which lead-poisoning was followed by well-marked symptoms of gout, both being relieved by the use of opium and iodide of potassium.

MISCELLANY.

GOLDING BIRD ON IMBEDDING IN ELDER-PITH FOR CUTTING SECTIONS.—C. H. Golding Bird (*Quarterly Journal of Microscopic Science*, January, 1875) finds elder-pith, much used in former years, a very favorable imbedding material for cutting sections. The principle recommended by the author is the same as that adopted by Ranvier, viz., the swelling of the parenchymatous tissue of the dried pith in the presence of moisture. The object to be cut is placed in elder-pith, and this is fitted into Ranvier's microtome. If water be poured upon it, the pith will have swollen in a very short time sufficiently to hold the specimen firmly in its place. "As to the quality of the sections obtained, I am almost converted," says the author, "to the belief that it matters but little, except in one or two cases, how or in what one imbeds, but that a good result is rather owing to the skill and ingenuity of the manipulator in each particular case. Every one upholds, naturally, the way in which he himself is accustomed to work, and rightly so."—*London Medical Record*.

THE PROFESSION IN FRANCE.—The number of medical men in France seems to remain stationary. In 1847 there were 10,643 practitioners, or one to every 3244 inhabitants. In 1866 there were, taking in the annexed departments, 11,525, still, by a singular coincidence, averaging one to the same number of inhabitants above cited. In 1872, when Alsace and Lorraine were lost to France, there were only 10,766 doctors, or one to each 3353 inhabitants. This dearth of medical assistance is attracting considerable attention in France, and is likely before long, according to the *Revue Scientifique*, to become the subject of legislative interference. The unequal distribution of the available number of medical practitioners renders the situation all the more serious: for instance, in the department of the Seine there is a doctor to every 1115 inhabitants, whilst in the department of the Morbihan there is only one to each 10,576 of the population,—a scarcity of medical aid which is surpassed in the case of one department, which rejoices in the medical care of one practitioner only for 11,000 people.—*London Medical Record*.

FEMALE OBSTETRICIANS.—Notwithstanding a few plausible arguments that may be adduced in favor of female obstetricians, it is, we think, a moot point whether obstetrics is not, after all, the very department of medical and surgical practice for which women are morally and physically least fitted. Perhaps, indeed, the strongest disqualification of the female obstetrician is the moral; but the physical incapacity of women is more apparent. No one who knows anything of the arduous and anxious duties of the obstetrician, of his exposure to rude and inclement weather, or of the serious contingencies of midwifery practice, is justified in seriously encouraging women to enter upon this field of labor.—*London Lancet*.

THE value of sponges collected this season on the Florida reef is estimated at \$165,000.

PURVES ON THE PLACE WHERE THE WHITE BLOOD-CORPUSCLES WANDER OUT OF THE VESSELS.—L. Purves (*Onderzoekingen gedaan in het Physiol. Labor. Utrecht*, 1873, iii.), to investigate the place where the white blood-corpuscles pass through the wall of the vessel in Cohnheim's experiment on inflammation, injected a solution of silver into the vessels of a frog prepared after the manner of Cohnheim. The colorless corpuscles, without exception, wander out between the boundaries of the epithelioid cells. They never pass through the substance or through the nucleus of an epithelioid cell. According to the author, the red corpuscles only pass out by those channels which have been previously made for them by the colorless corpuscles. The author found no stomata of any kind on the epithelium of the vessels.—*London Medical Record*.

ACCORDING to the *Pharmaceutical Gazette*, M. Hayduck has been investigating orthoamidotoluenesulphonic acid, and diazorthoamidoparatoluenesulphonic acid; the same authority also affirms that the action of tin and hydrochloric acid on nitro-bromacetanilide gives rise to the hydrochloride of ethenylbromophenylenediamine.

DR. W. R. GILMORE, Ambulance-Surgeon at the Reception Hospital, New York, recently died from the effects of a curious accident. Owing to an icy sidewalk, he fell upon the point of his umbrella, which penetrated the orbit.

NOTES AND QUERIES.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—One and one-half grains of digitalis were administered every two hours, and not half a grain, as stated, in the case of Mr. T., published Jan. 23. A. K. MINICH.

SCHUYLKILL COUNTY MEDICAL SOCIETY.

At a regular stated meeting of the Schuylkill County Medical Society, held at Pottsville on Wednesday morning, Jan. 6, the following officers were elected:

President, Dr. G. K. McKibbin, Ashland.
Vice-President, Dr. A. P. Carr, St. Clair.
Treasurer, Dr. W. H. Senderling, Port Carbon.
Secretary, Dr. R. S. Chrisman, Pottsville.
Corresponding Secretary, Dr. J. J. Yocum, Ashland.
Censor, Dr. W. R. Owens, Ashland.
Doctress Mary A. Swayze was elected a member of said Society.

Dr. A. P. Carr read a very interesting paper on Croup, and presented a specimen of false membrane showing a perfect cast of a part of the bronchial tubes.

NORTHERN MEDICAL ASSOCIATION OF PHILADELPHIA.

A stated meeting will be held at the Hall of the Northern Dispensary, 608 Fairmount Avenue, on Friday evening, February 26, at 8 o'clock.

Subject for discussion: "Anomalies of Refraction," with exhibition of new instrument for determination. To be introduced by Dr. S. D. Risley.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM FEBRUARY 2, 1875, TO FEBRUARY 8, 1875, INCLUSIVE.

BENTLEY, EDWIN, ASSISTANT-SURGEON.—To proceed to Camp Bidwell, Cal., for temporary duty at that post, and, upon its completion, to return to his station in San Francisco, Cal. S. O. 11, Department of California, January 25, 1875.

SATURDAY, FEBRUARY 20, 1875.

ORIGINAL LECTURES.

ON THE PRINCIPLES WHICH GOVERN THE USE OF ELECTRICITY IN MOTOR PARALYSIS.

An Abstract of a Course of Three Lectures delivered at the University Hospital.

BY H. C. WOOD, JR., M.D.

LECTURE III.

GENTLEMEN,—In our previous lectures we have sufficiently studied the laws of galvanic currents, their effects upon normal muscles, and the methods of their application. To-day we shall consider directly their use in disease. I shall not try to point out in what palsies you shall employ them, but rather give you such principles as will enable you to make your own deductions as to individual cases.

Galvanic currents are employed in paralytic affections for three distinct purposes,—namely, diagnosis, prognosis, and therapeutics. These I shall consider in the order in which they have been enunciated.

There are certain palsies, such as pseudo-muscular hypertrophy, in which the muscular structure is so destroyed independently of any involvement of the nervous system that no response to the galvanic current is possible. All of these palsies are, however, essentially exceedingly chronic, and their diagnosis is to be made out chiefly by a microscopical examination of the muscles themselves. As electricity does not come into play in the diagnosis of these cases, I shall not say more about them. It is otherwise with suddenly-developed paralysis in which the history does not point to any immediate cause, as diphtheria. Often, in such cases, galvanism is of great diagnostic value. As stated in a previous lecture, when a muscle is entirely deprived of the influence of the spinal centres it rapidly loses its electro-contractility, whereas, if a muscle be paralyzed from a lesion of such character or position as not to interfere between it and the trophic cells of the cord, it maintains its integrity for many weeks. When a muscle is degenerating for want of spinal influence, it first loses its power of responding to rapidly-interrupted faradic or chemical currents, then to slowly-interrupted faradic currents, then to slowly-interrupted chemical currents, and lastly to slowly-reversed chemical currents. When, therefore, a muscle loses its power of responding to the rapidly-interrupted faradic current in a week or ten days after the occurrence of paralysis, the inference is very positive that the lesion is either one of the nerve-trunk, or, being of a nerve-centre, is of such a character as seriously to involve the trophic cells of the spinal cord. If a few days later such muscle is unable to respond to any faradic current, this inference becomes a certainty. Under these circumstances the possible lesion is narrowed down to infantile paralysis, a conceivable

destructive myelitis, and an affection of a nerve-trunk.

A *myelitis* so rapid and severe as to destroy in a few days a portion of the spinal cord, and consequently the electro-contractility of its tributary muscles, is exceedingly rare, and, if it occurred, could offer no difficulties of diagnosis. In *infantile palsy* the nature of the case is usually but too apparent, although the muscles often lose their electro-contractility as quickly as when a nerve-trunk is severed. Practically, therefore, very rarely is there any difficulty in recognizing the seat of the lesion in acute organic palsies by means of the galvanic test. It may be laid down as a practically invariable rule *that when in the adult a muscle loses to a sensible degree in a few days its electro-contractility, the lesion is in a nerve-trunk.* In recognizing, however, these peripheral palsies, it must not be forgotten that the injury to the nerve may be very deeply situated; even within the membranes or substance of the nerve-centres. This is especially to be borne in mind when it is a cerebral nerve that is affected. Thus, a tumor situated in a superficial portion of the brain may press upon the fibres of a nerve just as they are collecting together previous to leaving the brain, and the result will be a palsy which is really a peripheral one, although the tumor is in the nerve-centre. The persistence of the muscular contractility intact for some weeks after the occurrence of a palsy depending upon an organic lesion, proves that the disease is of cerebral origin, or, being spinal, is of such nature as not to compromise seriously the trophic nerves of the cord.

In applying these rules, you must not forget that whenever a muscle is not used it loses its contractile power, so that even in paralysis from cerebral hemorrhages the muscles finally degenerate, although this degeneration is rarely so complete as in peripheral palsies. It is not the fact of degeneration, but its degree, and especially the period of time which elapses between its occurrence and the commencement of the paralysis, which is the important factor in the diagnosis. In cerebral palsies no distinct loss of functional activity in the muscles is usually perceived sooner than six weeks after the onset of the attack, and even after years have elapsed some response is usually elicited by strong slowly-interrupted or reversed currents.

There are certain palsies in which the electro-muscular contractility is really or apparently above normal. Very frequently the excessive contractions produced are not so markedly in the muscles to which the currents are applied as in other muscles, whose movements are in reality reflex in their nature. In all these cases the probabilities are that there is a condition of acute hyperæmia or of excessive functional irritability of the spinal cord.

In regard to certain so-called functional palsies, the muscles in *lead-paralysis* very generally lose their electro-contractility, and, curiously enough, according to my own observation may recover to a marked degree the power of voluntary motion, without a corresponding restoration of their normal electrical relations.

In *hysterical paralysis* any aid to diagnosis is often of very great value; and it has been asserted that in this class of palsies the preservation of electro-contractility with loss of electro-sensibility is always present, and is of diagnostic value.

My experience, however, is very positive that in hysterical palsy both electro-contractility and electro-sensibility are frequently normal. When, however, in any case the muscle responds to galvanic currents, although the patient is to a great extent, or altogether, insensible to their passage, a very positive diagnosis of hysteria may be given. The electro-contractility is never seriously compromised in hysterical palsy.

In using galvanism as an aid in *prognosis*, the condition of the muscular contractility is always to be considered in conjunction with the nature of the lesion and the length of time it has existed.

Taking first ordinary *hemiplegia* as the type of *cerebral* palsies, it must be borne in mind that the actual existent amount of paralysis is really the product of two essentially different factors. The nerve-centre is primarily damaged, and after a time the muscle also suffers loss of structural integrity from want of use. The restoration of the nerve-centre does not necessarily involve the restoration of the muscle, so that in a case of hemiplegia of some standing, the cerebrum may have recovered itself partially or entirely, and yet the muscle be in such a state of degeneration as to be unable to respond to the impulse transmitted to it from the nerve-centre.

Under these circumstances, galvanic treatment, although unable to affect to any extent the nerve-centres, does great good by restoring the muscular tone. It is manifestly impossible in such a case to determine before treatment how far the nerve-centre has recovered itself, or, in other words, to what extent the existing paralysis is of centric and to what extent it is of muscular origin. When, in a case of apoplectic hemiplegia, there is no recovery at all of the power of voluntary movement after the lapse of six weeks, the prospect of decided improvement from electrical treatment is very gloomy, because the probabilities are altogether in favor of the existence of a serious, persistent centric lesion. If, however, there is some motion, the probabilities of improvement are inversely proportionate to the structural health of the muscles. If the tone and the electro-contractility of these are normal, the centric factor is the chief one in the production of the paralysis, and little good is to be achieved by the use of the galvanic current. On the other hand, if the muscles have undergone a very decided degeneration, much good is to be expected. No hopes of absolute cure should, however, be held out, because in the great majority of cases, after the muscles have been fully restored, the nerve-centre is found to be more or less damaged. The improvement is usually at first rapid, but after a time ceases altogether, because, the muscles having recovered their tone, it is not possible to affect, to any great extent, the sole remaining cause of the paralysis, *i.e.*, the centric lesion. Under these circumstances it is useless to continue treatment.

In *infantile paralysis*, early in the attack the galvanic current is of little value in determining the prognosis, excepting that the general law is, that the more rapidly electro-contractility is lost, the more serious is the case. In advanced cases, the length of duration and the condition of the electro-contractility in the muscles are both to be considered. If no response at all to an electric current can be obtained, the prognosis is always very grave; although even under such circumstances a decided improvement has occurred in a small percentage of the cases I have treated. If the case be an old one, the preservation of some degree of electro-contractility indicates that the structural lesion in the cord is not a fatal one, and as, under these circumstances, the muscles can always be more or less perfectly restored, the prospect of improvement is a very certain one. The preservation of electro-contractility late in the disorder, when the centric lesion is no longer progressing, is of much more import than it is in the first few weeks or months of the case, when the central trouble may be increasing.

In *peripheral palsies* the prognosis depends rather upon the nature of the nerve-lesion than upon the condition of the muscle; but it must be remembered that when a muscle has absolutely lost its power of responding to any electrical current, its restoration is always a matter of difficulty and of doubt.

In regard to *therapeutics*, the first point to be determined in acute cases is very often when to commence electrical treatment. When the lesion is of such nature as not to provoke any irritation of the nerve-centre, no time should be lost. Thus, if a man is unable to use his arm because he has slept with it under his head and thereby paralyzed the nerve by pressure, the electrical treatment should commence at once.

When, however, the lesion is of such character as of necessity to irritate the nerve-centres, the case is different.

The local stimulation of the peripheral nerve-fibres by electrical current does, in some way not yet definitely understood, affect the nutrition of the nerve-centres; and when these nerve-centres are in a state of active excitement or inflammation, a peripheral galvanic irritation may do serious injury to them. Hence the rule that where an acute palsy is connected with active irritation of the nerve-centres, galvanism should not be used upon the muscles until the centric disturbance has subsided. Thus, in *hemiplegia* from cerebral hemorrhage the muscles must be allowed to rest until not only all symptoms of centric irritation have subsided, but until the brain has become so accustomed to the clot that the latter no longer acts as a foreign body. It is usually from three to six weeks before electricity can be used with advantage in these cases. Again, in acute *cerebritis*, *cerebral or spinal meningitis*, and *myelitis*, the use of galvanic currents should be strictly forbidden until a stage is reached when the effects of the inflammation, and not the inflammation itself, are to be dealt with.

When it has been decided to commence the use of galvanism, it is next to be determined what cur-

rent shall be used. You will remember that I have demonstrated to you that there are no inherent mysterious differences in the various currents; yet there is a practical difference, and the clinical rule of choice is, *Always select that current which produces the most muscular contractions with the least amount of pain*; trying the rapidly-interrupted faradic, or, if you have only a chemical battery, chemical current, and the slowly-interrupted faradic or continuous current, and always, when these fail to elicit response, the slowly-reversed chemical current, which, if necessary, may be increased in strength until the patient can no longer bear the pain.

The current having been selected, the individual muscles must be galvanized at each séance.

After what has been said in a previous lecture, it is not necessary to speak to you concerning the best methods of applying the currents to the muscles; but, remember, it is not the electricity directly, but the contractions induced by it, which benefit the palsied parts.

There are certain precautionary rules which must never be lost sight of in the galvanic treatment of palsies. Pain is an evil, and its infliction is always to be avoided as far as possible. Hence the rule never to use stronger currents than is necessary. It is very possible to fatigue a healthy muscle, much more a diseased one. A weak muscle may be greatly injured by being over-fatigued. Hence the rule that currents are not to be applied to muscles so long at one time as to induce fatigue. In general, an electrical séance should last from ten to twenty minutes, no one muscle being subjected to the currents for more than five minutes.

ORIGINAL COMMUNICATIONS.

TWO CASES OF CONGENITAL DEFORMITY.

BY H. C. HAND, M.D.

I. IMPERFORATE ANUS, THE RECTUM OPENING INTO THE VAGINA.

ON the 10th of March, 1874, there was born, of middle-aged and healthy Norwegian parents, a child with the above malformation. It was plump and healthy, and did not seem to be inconvenienced by the abnormal point of discharge for its fæces. At the place where the anus should have been there was a small teat-like projection. A short distance above the hymen the posterior vaginal wall was found wanting, and was absent from this point up to the uterus, the os uteri looking directly into the rectum.

The case was in the medical care of Dr. C. E. Smith, who requested me to undertake its surgical conduct.

On the 3d of April, assisted by Dr. Smith and Dr. D. W. Hand, an attempt was made, as follows, to establish an anus in its natural location. A crucial incision was made through the skin and subjacent tissue to the depth of about three-fourths of an inch; the yielding intestinal wall, being now reached, was steadied by passing the little finger of the left hand in through the vagina upon it, and then divided. The mucous membrane was brought down and stitched to the skin as well as might be; but this was very imperfectly, for, as the anterior wall of the rectum was absent, there was, of course, at that part no mucous membrane to bring down. The

rectum formed no pouch below its opening into the vagina, but made a direct course into that canal.

An anus was thus made sufficiently large to admit the little finger. A piece of wax bougie was tied in, and the patient left in good condition. Little or no reactionary fever followed. The bougie was removed, reintroduced, and worn without difficulty until towards the close of the first week, when the mucous membrane, having let go its adhesions below, formed a valve at its original site, which prevented the upward passage of either the wax bougie or the finger.

A large bead was procured, somewhat larger than the desired size of outlet, and fastened to a stout ligature; the other end of the ligature was threaded in an eyed probe, bent into a semicircle. The probe was then passed in at the vagina and out at the anus, through the opening previously made. The probe and ligature were drawn through until the bead was fairly fixed at the termination of the natural rectum, where the valve-like process prevented communication with the incision upward from the anus. The bead was allowed to remain in this position, the ligature being fastened on the back just tight enough to hold it. Several times a day smart traction was made, after which the ligature was re-fastened as before. In three days the bead worked its way through, and came out at the anus. The little finger could now be readily introduced, and from this time onward the mother found no difficulty in introducing her little finger daily. A curious complication arose about four weeks after the operation, in a copious eruption of vaccine vesicles in and about the anus.

Another child at the same time had a vaccine scab on his arm, from which the mother unconsciously vaccinated the baby in this undesirable location. The incision became ulcerated in its entire extent, and for a time it was feared that the septum between the anus and the vagina would be destroyed. But the ulcerative action was stayed without working this mischief.

After the fretfulness from the vaccination wore off, the child did well in every way until the following November. At first, only a little of the fæces passed by the anus, but gradually more and more, until when it lay on its back all generally passed by the anus, while if it defecated when lying on its face more or less would always come through the vagina. Defecation was performed but little oftener than natural.

Towards the close of November, 1874, the parents noticed that the child was not so well as usual, and on the 10th of December it died of meningitis.

If the patient had lived, I think the opening between the vagina and the rectum would have closed spontaneously: at least it was making good progress to that end; or, if it should not have entirely closed, it would at least have become so small that its edges could easily have been pared and united when she had reached the proper age.

II. SPINA BIFIDA WITH CLUBBED FEET.

Mrs. B., a healthy Irishwoman, and the mother of several fine children, on the 10th of January, 1875, after a labor consisting of but one pain, gave birth to a medium-sized and well-nourished child, deformed as follows: In the middle line of its back, opposite the middle lumbar vertebræ, was a flattened rose-like tumor, one and a half inches across its top, one-half inch in height, and having a constricted base. On its base and sides this tumor was covered with skin, but on the upper flat surface the skin was absent, and the appearance given was that of folds of delicate mucous membrane intensely congested, having a purplish hue. This was doubtless an outgrowth from the coverings of the spinal cord. About the centre of this rose there was a depression, from which a few drops of clear liquid frequently escaped.

The muscles of the front of the child's legs and thighs were so much contracted that the legs were constantly held in front of the chest, with the toes almost touching the shoulders. They could be drawn down nearly into a line with the body, but, when let go of, sprang back into their strange position. The knees were so drawn that they bent forwards instead of backwards, the legs and thighs almost forming a semicircle with the convexity at the back of the limb. The toes of each foot were forcibly drawn up towards the ankle, the heel being thus forced down. On one side the toes were strongly turned inwards as well as up, and on the other they were as strongly turned outwards and up.

The anus was pouting and patulous, and fæces were passed frequently and in large quantities.

The child took milk heartily, and seemed to flourish for a week, when, without any unusual escape of cerebro-spinal fluid, or any convulsion, it quite suddenly got cold, seemed to be in severe pain, and died. Unfortunately, there was no chance to examine the body after death, and to preserve its singularly contorted form.

ST. PAUL, MINN., January 28, 1875.

SULPHATE OF QUININE IN PREMATURE LABOR.

BY HARVEY L. BYRD, M.D.,

Late Professor in the Savannah and Oglethorpe Medical Colleges of Georgia, and the Washington University, and College of Physicians and Surgeons of Maryland, etc., etc.

THE following case, having interested the writer to a considerable extent, illustrating and establishing, as it does, more completely the antiperiodic action of one of our most esteemed and reliable remedies, is deemed of sufficient value and importance to the profession at large to warrant its publication in the pages of the *Medical Times*. There has appeared from time to time a disposition on the part of some practitioners to attach parturient properties to the salts of quinine, and particularly the sulphate; and cases have been reported in order to strengthen the idea of its action in that regard. The weight of professional opinion has not preponderated in that direction, however, as may be seen in the daily prescription of this drug in malarial fevers, and, in fact, in all diseases of marked periodicity in their character, without fear of its exerting injurious action on the uterus in regard to gestation. So far from any apprehension of its producing uterine contraction, it is often prescribed for the purpose of lessening irritability of that organ. In a professional experience extending over a period of more than thirty years, in all forms and varieties of disease in which quinine is indicated, I have prescribed it alone, or in combination with such other articles as seemed necessary, not only without injury to the pregnant female in all stages of gestation, but with marked and positive advantage in those of threatened abortion and premature labor. With this experience in regard to its *modus operandi*, no difficulty was encountered in selecting it as the leading article in the treatment of the particular case soon to be mentioned.

In an office-consultation with Mr. D., one of the most reliable and enterprising merchants of Baltimore, the following facts were elicited in regard to his wife. She was represented as being in the

seventh month of utero-gestation, and as having had seven successive premature deliveries at the eighth month of pregnancy; and all the children died at or a few hours after birth, except one, which was kept alive, with great difficulty, until the eighth week.

Having been thus unfortunate under the care of other physicians, it was thought that a change to another might give "better luck" this time, and, possibly, the unfortunate eighth-month habit broken up. Learning thus much from Mr. D., his wife was visited the following day, July 12, 1874. She was found to be an intelligent, healthy-looking young lady, of about thirty-two years, sanguine temperament, medium height and size. She stated that in previous pregnancies she had been carefully attended by her physicians, but did not know much of the treatment pursued, beyond the general facts that she had been constantly kept in a recumbent or reclining position for three or four weeks prior to her expected confinements, and almost continuously under the influence of morphia or opium during those periods. This was the general course pursued in all her pregnancies after the second, with the results above stated. The following constituted the course of treatment recommended and continued with the most satisfactory results. Three weeks in advance of her usual mishap, she was directed to surrender the entire care of her domestic affairs into the hands of another, to confine herself to the limits of her bed-chamber, and as much as possible to her bed.

℞ Pulv. aloes Socot., ʒi;
Pulv. rhei, ʒss;
Podophyllin., gr. v;
Bicarb. sodii, gr. vi;
Ext. nuc. vom., gr. iv;
Ol. menth. pip., gtt. i.

Make thirty-five pills. S.—One pill at bedtime to keep the bowels open. During the day, and commencing at 5 A.M., one of the following pills every four hours, until *quininism* is induced, or until four have been taken: ℞ Sulph. quiniæ, ʒss. Make eight pills. Should nervousness occur during the day,—to which she was somewhat subject,—valerianate of quinine in one-grain doses to be substituted for the sulphate. When restless or disinclined to sleep at night,

℞ Bromide potassium,
Hydrate chloral, āā ʒij;
Water, ʒiv.—M.

S.—Take a dessert-spoonful as occasion requires.

The foregoing treatment was continued with little variation, except an occasional dose of compound spirit of lavender when nervous symptoms were not relieved by the other remedies, until about a week after the dreaded crisis was safely passed, when she was permitted to read, sit up, and take gentle exercise about her room. At the commencement of the thirty-eighth week from her last menstruation, labor began, and progressed normally through all its stages, resulting in the safe delivery of Mrs. D. of a healthy and perfectly-formed female infant, of about eight

pounds avoirdupois, in ten hours after it began. This little miss had scarce emerged into the world ere she gave unmistakable evidence of her ability to maintain a separate existence, and probably no mother ever experienced more joy, or had greater hopes inspired by the cry of her new-born babe, than the happy mother on this occasion.

At the date of this writing the child is three months old, and is growing and prospering to the entire satisfaction of all parties concerned.

It is proper to remark, before closing this brief account of an unusually interesting case, that Mrs. D. was in no wise restricted in her diet during the treatment, except in regard to such articles as experience had proven indigestible.

366 N. FREMONT STREET, Jan. 26, 1875.

NOTES OF HOSPITAL PRACTICE.

ALLGEMEINES KRANKENHAUS, VIENNA.

CLINIC OF PROF. KARL BRAUN, NOV. 5, 1874.

CAULIFLOWER EXCRESCENCE—PORTION OF PERITONEUM REMOVED.

GENTLEMEN,—The patient we introduce to you to-day is a married woman, æt. 32, and has borne two children. Her physical appearance is good, and no one would imagine, judging from it, that she was suffering from any serious cachexia. Yet she is laboring under a difficulty which, if not promptly met and treated, will beyond a doubt be fatal in its results.

She tells us that for a period of five months she has been constantly losing blood, not in great quantity, it is true, yet there has been a steady drain upon her system, which threatens sooner or later to undermine her strength; and it is our purpose to-day to make an examination of the trouble, and to do something for its removal.

A vaginal examination reveals, situated upon the anterior lip of the cervix more especially, yet extending nearly the entire distance around it, a new growth, which we have no hesitation in pronouncing, from the peculiar sensation it imparts to the fingers, the hemorrhage which accompanies it, and the entire history of the case, to be an instance of the so-called "cauliflower excrescence."

What, in such a case, should be our treatment? Experience has conclusively proven that nothing short of its radical removal will be of any value. Any attempt short of this will result in a failure, and the condition of the patient subsequently will be even worse than at present. Here it is always better to cut away too much tissue than not enough. A portion of the peritoneum may be removed, proper care being taken in the subsequent treatment, and yet no injury result. In the very many cases here operated upon in the past twenty years, but a very small percentage has been lost, while in many of these the peritoneum has been cut. I operate every year fifteen or twenty times for this difficulty, and often remove a portion of the peritoneum so large that my assistants scratch their heads and say, "He has gone too far this time;" but as they grow older and see these operations again and again repeated with most favorable results, they learn better. The surgeon would object to such an operation, involving the opening of the peritoneal sac, but the gynecologist, who operates in this region much oftener, knows better what can be done.

As to the instruments used in this operation, I have

little at present to say. The operator will be guided by the conditions of the case, or, it may be, by taste, in choosing them. I prefer in these cases the use of the galvano-caustic to all other means, and place the wire so that it shall pass through *perfectly healthy* tissue.

[The operation was here performed, and a large portion of the cervix amputated, the wire passing completely behind the growth, which was about as large as a hulled walnut, removing a portion of Douglas's cul-de-sac.]

You will observe, gentlemen, as this specimen passes around the class, that I have removed quite a considerable portion of peritoneum. It is better to avoid doing this, if possible. I do not think this case required it, and had not intended to touch it, but the folds of the posterior wall of the vagina deceived me. Our subsequent treatment will be very simple. We will use a glycerin tampon, taking care not to introduce it so far that there would be danger of its passing into the abdominal cavity; and no injection whatever will be allowed. The patient will be required to lie as much as possible on her back, the severed tissues being thus thrown more nearly into accurate juxtaposition, and the healing process will be proportionately more rapid.

Nov. 14.—Patient doing very well. There has been no rise in temperature since the operation.

VERSION FOLLOWED BY CRANIOTOMY.

We introduce another patient to you, gentlemen, in labor. She is 23 years of age, strong and healthy; is a primipara; has had strong labor-pains since yesterday, and she is brought into the clinic because my assistant informs me he is not satisfied with the progress the case is making. We will make a vaginal examination, to ascertain in what way be found the difficulty. We find here on introducing the index-finger a conjugate diameter less than that of the normal pelvis, measuring two and three-quarters or at most three inches; a cervix very much elongated, measuring four inches in length, and the external os as yet very imperfectly dilated; a head large and high up, not yet descended into the pelvis, and having the left occipito-anterior position.

We find here, then, conditions which demand our assistance, without which there may occur paralysis or inflammation of the uterus or its rupture. There are here as yet no signs of a rupture of the cervix; but that may take place under conditions which are not usually supposed capable of producing a rupture. I have had a case of premature labor in which rupture of the cervix occurred, the head being only two inches in its biparietal diameter.

I shall here lay the patient upon her right side, and, introducing my left hand, the palm corresponding to the abdomen of the child, endeavor to reach a knee. I find this, however, impossible, and shall introduce my right hand, the patient retaining the same position. I succeed in grasping a foot, and, as you see, bring it down while I pass over it a sling. As the pains again come on I make strong traction on the limb, while my assistant aids me by making pressure on the fundus and sides of the uterus, and we extract as far as the buttocks, when we cease making traction, the gradual extrusion of the body being very necessary for the proper expansion of the mother's soft parts,—the vulva and perineum. The shoulders now having come to the outlet, my attention is directed to the extraction of the arms. Here I find at once that I am unable to deliver the arms in the usual manner by drawing them downward over the face and breast of the child. Both are drawn upward and behind the head, where they are crossed, giving us an instance we do not often meet with, and in which it very frequently becomes necessary to fracture the arms if we would deliver promptly

enough to save the life of the child. In twenty-five years of practice I have had two cases in which I have fractured the arms for this reason. In such unpleasant and yet occasionally unavoidable accidents, treatment by a plaster bandage is very efficacious, and in a month nothing of the fracture can be remarked. Having brought down the arms, we find the head delayed, and all attempts I can make at extraction by manipulation are unavailing. It is very evident that this child cannot be born alive. The pulsations of the cord have already ceased, and no heart-sounds are to be detected. Delivery, however, must not be delayed, and we will at once proceed to the extraction of the child by means of the trepan and cranioclast. Many affirm that we cannot apply these on the after-coming head; but practice says otherwise. I never apply the cephalotribe in these cases, believing that we have in the *curved* trepan and Simpson's *lengthened* cranioclast much more efficacious instruments. The cranioclast preceded by perforation accomplishes all that is necessary. For ten years we have found this Simpson's *lengthened* cranioclast to give more satisfaction than any other, and for twenty years we have found no trepan so good as the one we show you. The fewer instruments you use, the better. In this hospital we find a necessity for only two destructive instruments, which are those we show you, and they, aided by the hand, prove sufficient for every emergency. Considering that from 1849 until 1856 we had four thousand cases of labor annually, and since 1856 five thousand cases annually, we have had a good opportunity of testing different instruments. The cephalotribe I have entirely abandoned, after a long and faithful trial of it under its various modifications.

Introducing the trepan, I pass it into the cranium through the occipital bone, and, applying the cranioclast, the head is extracted without difficulty.

In these cases I always prefer turning before performing craniotomy, because, when the operation is performed while the head is presenting, the movements of the child in the agonies of death can be very distinctly felt, and it may, and often does, live after being extracted. Turning, however, is not to be readily accomplished in these cases without good assistance; and had I not here the co-operation of experienced hands I would not have attempted it. It may be performed after perforation without risk of injury to the soft parts of the mother.

There has been here no rupture of the cervix, no laceration of the tissues, and no metritis, and we are justifiable in hoping for a rapid recovery. This woman should be placed in a large, well-ventilated, and quiet room, where she will be exposed to no danger of infection from patients suffering from metritis, peritonitis, etc., and in eight or ten days will be rapidly convalescing.

If she should again be pregnant in the future, she should be examined every month during the second half of the pregnancy, and when the child has attained a weight of four or five pounds, or about the thirty-fourth or thirty-sixth week, premature labor should be induced.

Nov. 14.—Patient doing well.

G. WILDS LINN.

RELATION BETWEEN RACHITIS AND SYPHILIS (*The American Practitioner*, February, 1875).—Dr. R. W. Taylor, after considering the relation between these two diseases, says that he is prepared to admit that syphilis may be one of the causes of rickets, but that there is no specific relation between the two diseases; that syphilis may remotely cause rickets by its lowering effects upon the organism, in the same manner that any adynamic influence might produce the same effect.

TRANSLATIONS.

TANNIN IN THE CORYZA OF ADULTS AND CHILDREN.—"You are constantly telling us," it is sometimes said, "of the great progress made in recent times by medicine, and you have not yet found out, from the time of Hippocrates until now, the means of curing coryza." Those who reproach us in this way forget to add that, not wishing, for the sake of curing a simple "cold in the head," to submit to any of the hygienic measures rationally indicated, they demand in reality a prompt means of cure, easy to follow, even while travelling. Even those who cry up infallible specifics most loudly have never proposed anything more than some palliative, and these, from ammonia to iodine, are always in a liquid form, just the shape which is most difficult and inconvenient to carry about. In general, all these preparations are far from compensating by their utility for the inconvenience of their employment.

For ourselves, who do not intend to change our habits or suspend our business any longer for the sake of a coryza, every time we have been attacked by our enemy we have put the question upon a practical footing, and have endeavored no longer to cause the disease to disappear instantaneously by some sovereign *specific*, but to diminish its principal inconveniences and to render its attacks in some degree tolerable.

Observe how we have attained our object. The first symptoms of coryza are congestion of the mucous membrane of the nasal fossæ, with dull headache, heat in the upper part of the face, sleepiness, dryness of the mouth and throat, more noticeable when swelling of the mucous membrane closes the nasal passages completely, obliging the patient to breathe with the mouth constantly open. Such are the principal tortures of a "cold in the head," and for which relief is most urgently demanded. It is evident that if an energetic contraction of the mucous membrane can be brought about, so that its volume shall be diminished, this desideratum can be attained. In short, when the air finds a free passage through the nasal fossæ, the frontal headache and the lachrymation will disappear, and at the same time the dryness of the mouth, which may then be kept closed.

In addition, the mucous membrane being compressed like a sponge, makes easy the expulsion of those fluid mucosities which cannot be detached under ordinary circumstances without great effort.

We may obtain these results constantly by the use of tannin made into a powder after the following formula:

R Tannin., gr. $\frac{3}{4}$;
Pulv. iris,
Pulv. althææ, ãã gr. xv;
Tinct. vanillæ, gtt. iv.—M.

To be taken in small pinches three or four times a day, or oftener if necessary.

Coryza, which in the adult merely presents inconveniences easy to support, becomes, on the other hand, a serious matter when it attacks an infant. Here, as all physicians know, the occlusion of the nasal fossæ may directly threaten life, because rendering efforts at suction of the breast impossible. It is necessary to act immediately; and it must be confessed that the means heretofore recommended have proved totally inefficacious. Observe our method of combating the danger.

After having prepared the following ointment,

R Tannin., gr. $\frac{3}{4}$;
Axungiæ, ʒi ʒi;
Tinct. vanillæ, gtt. v.—M.

we roll between the thumb and index-finger a very small square of paper so as to form a not very rigid

cylinder, which will yield easily to any lateral movements which may be made by the infant while it is being introduced into the nostrils. Then, after having smeared the exterior with the ointment, it is introduced deeply into each nasal fossa.

In this manner we often bring about one or two very salutary attacks of sneezing, and always the effect just noticed as occurring in the adult, that is to say, free circulation of air in the nasal fossæ following the subsidence of swelling in the mucous membrane. The parents are always struck with the rapidity with which the infant returns to the breast, thanks to the success of this little manœuvre. It is because we are convinced that we have rescued more than one infant from imminent danger that we lay stress upon the process which has demonstrated to us that, in the medical treatment of infancy, it is the trifling appliances which often produce the best effects.—Dr. D., in *Tribune Médicale*, Jan. 17, 1875. X.

THERAPEUTIC NOTES.

MASSAGE IN ABSCESS OF THE CORNEA.—In the *Independencia Médica*, of Barcelona, Dr. Osio recommends the application of massage in abscess of the cornea. He says that every one unconsciously practises it when rubbing the eyes. At the Ophthalmological Congress of 1872, held in London, Donders called attention to the practice as one that had yielded him excellent results. Dr. Osio has employed massage of the cornea with success in certain diseases of the eye. He has more recently combined the use of aqueous vapor with massage. He employs the following method: An apparatus charged with an infusion of chamomile is placed before the patient's eyes (which have previously been covered with a double layer of fine muslin) at such a distance that the vapor reaches the eyes at a temperature of from 90° to 100° F. At the same time massage of the eye should be performed with the fingers over the muslin, rubbing it up and down, from side to side, and finally by a circular movement pressing upon the centre of the cornea. At intervals the apparatus may be brought nearer, so that the eyes may for a few moments be subjected to steam of a higher temperature than that indicated. This vapor-bath should be continued for a half or three-quarters of an hour, and during this time the massage should be repeated from eight to ten times, with a duration of from one to two minutes upon each occasion.

MASSAGE IN SPRAINS.—M. Fontaine writes (*Archives Méd. Belges*, iii., 1874) on the use of massage in sprains. He has himself had great success. M. Fontaine first covers the limb with oil, and the part is rubbed with one or both thumbs, in gentle movements, from the extremities upwards, following, in general, the direction of the muscles and tendons. The affected, painful spot is rubbed gently, but the healthy neighboring parts more energetically, and the muscles at times thoroughly kneaded. This manipulation lasts from a quarter to half an hour, and is repeated three times daily. In the interval the limb is raised and bandaged. M. Fontaine thinks that the massage acts by spreading the blood extravasated (through rupture of vessels) over a large surface, and thus promoting absorption. But, whatever may be the *modus operandi*, M. Fontaine has obtained good results in sprains by the application of massage.

ACCORDING to *The Doctor*, February 1, a death has occurred in France from the intravenous injection of chloral.

CHLORAL AS AN APPLICATION IN GANGRENE.—M. Dujardin-Beaumetz communicated to the Société des Hôpitaux, at a recent sitting, an account of the case of a young man eighteen years of age, who applied for relief for spontaneous gangrene affecting the hand and fore-arm. In order to dissipate the odor, and to avoid the danger of septicæmia as far as possible, M. Beaumetz had the affected limb kept constantly in a bath containing one part chloral to five hundred parts water. At the end of eight days the arm was amputated, with a favorable result.—*Medical Press and Circular*.

ANTIDOTE FOR PHENIC ACID.—The editor of the *Pabellon Médico* strongly commends M. Husemann's procedure in regard of employing the alkalies and alkaline earths, and more especially the saccharate of lime. This is readily prepared by adding five parts of caustic lime to a solution of ten parts of sugar in forty of distilled water, and leaving it to digest ten days before filtering.—*The Doctor*.

TYPHOID FEVER.—M. Valette read before the Société de Médecine a *résumé* of twenty-one cases of fever treated by Brandt's method of cold immersion. All the cases did well. Among the rest was a child of eleven, in whom typhoid fever had supervened on whooping-cough. The whooping-cough disappeared, but returned during convalescence.—*The Doctor*, from *Lyon Medical*.

LOCAL ANÆSTHESIA IN CASES OF LABOR.—Dr. Friedländer relates (in *Deutsche Klinik*, No. 30, 1874) that, being called to a woman who was suffering intolerable pain in the sacral region, he resorted to an application of chloroform (one part) and ether (two parts), after having vainly tried several other means. He obtained by this means total cessation of all pain until perfect delivery. After having successfully tried the same application in a great many cases, he recommends its employment as an anodyne for the pains of parturition.

IN RACHITIS.—

R Calcis phosphatis, ℥i;
Sodii carbonatis, ℥ii;
Sacch. lactis, ℥iii.—M.

Two or three pinches of this with the child's food three times a day, combined with cod-liver oil, saline baths, frictions, etc.

ALKALINE CHLORO-ALBUMINATE OF MERCURY FOR HYPODERMIC USE.—

No. 1.

R Hydrarg. chlor. corros., ʒvj ðij;
Ammon. chlorid., ℥iv;
Sodii chlorid., ℥i;
Aque destillat., ℥iv.

Dissolve and filter.

No. 2.

Dissolve the white of an egg in 4 oz. distilled water; filter.

Mix the two solutions, and filter; ℥xii contain about $\frac{1}{16}$ gr. of the mercurial salt.

A NEW POULTICE.—Carrageen is recommended by a committee of the French Academy as a substitute for flaxseed meal in poultices. It should be cut into thin plates of the size required, and when steeped in hot water it softens and swells in a few minutes. This new poultice has been tried by MM. Demarquay, Gosselin, and Verneuil in their respective hospitals, and they have pronounced it to be far superior to the linseed poultice; it keeps moist for more than sixteen or eighteen hours; it does not slip; is inodorous, does not readily ferment, nor does it soil the linen or bed of the patient.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, FEBRUARY 20, 1875.

EDITORIAL.

THE AMERICAN MEDICAL ASSOCIATION.

WE desire to call attention to a letter in another column, which, from its intrinsic character, as well as from the high position of its author, and his knowledge of the important subject on which he writes, deserves a most careful consideration. We were somewhat surprised at the statement that the *Philadelphia Medical Times* had pronounced the last meeting of the American Medical Association a failure, as we were not aware of having used language warranting such a deduction. On consulting our file, the strongest expression we can find is, "We deny emphatically that the convocation was in any true sense representative of the American medical profession." We are under obligations to Prof. Gross for confirming this, for surely no one will claim that a body in which there were "very few delegates from the Eastern, Middle, or Northern States" represented the whole country. The meeting did, in truth, represent a *section* of the country, and failed therefore in being *national*. If, in the play of Hamlet, Hamlet be not on the stage, can Othello, Juliet, Romeo, King Lear, one or all, atone for the omission, behave they themselves never so nobly? It makes little difference whether five hundred or five thousand physicians were present, if they were all or nearly all from one portion of the country. We are also obliged to Prof. Gross for confirming our expressions as to one of the great causes of this absence of national

character: namely, the want of a central place of meeting.

There is a hyperæsthesia to criticism which may be the outgrowth of a sense of weakness or failure, and may be dependent upon the sufferers not being veterans in discussion. To the existence of such hyperæsthesia we attribute the feeling which, according to the personal statements of an ex-president of the Association, has gone abroad, that the *Philadelphia Medical Times* is hostile to the American Medical Association, although we have over and over again given in our adherence to it. We are not able to express ourselves more clearly than we did last spring (vol. iv. p. 555), when we wrote, "We are of those who believe in the necessity of some *central* organization which shall, so far as possible, represent the profession in the United States, and we intend, therefore, to uphold the American Medical Association as much as we are able." He is a very frisky logician who reasons that a journal is opposed to an institution because it criticises its management.

We believe that, in order for the American Medical Association to be *national* in its character, great care should be exercised in selecting its places of meeting, and that in order for it to be *respected* at home and abroad it should not yearly publish a mass of matter most of which any respectable editor would at a glance consign to the waste-paper basket.

We are as proud of our country and of its achievements as is any one, but have never felt that we were to be elevated either in our own respect or in that of our transatlantic friends by proclaiming this pride. Boys and young nations are very apt to brag of their achievements. We do not see why it is more necessary for us to wave the starry banner and shout hosannas over the American people than it is for the London *Lancet* or the *British Medical Journal* to act as showman to the British Lion. We had thought that at least our learned professions had outgrown this weakness.

The American Medical Association, as well as the American profession, is to be advanced not by studying its excellencies, but by trying to determine and remedy its defects, and he who points these out is a far better friend than he who smothers progress with overflowing praise. One of the reasons the British Association is so much more successful than ours, seems to us to be because it does not waste its funds in publishing volumes that are a byword of contempt with critics both public and private.

We are by no means through with this subject; but, as the space allotted for editorial is full, we

shall next week offer in all humility to the consideration of the leaders of the American Medical Association a few suggestions as to the causes of that want of success in sustaining a thoroughly national society which, according to the statements of Prof. Gross, seems recently to have attended their efforts.

LEADING ARTICLES.

THE USE OF COLD IN FEVER.

NO. II.

THE clinical evidence in regard to the use of cold in fever may be looked at in two different ways. Thus, we may consider the assertions and results of individual observers, who have seen large numbers of cases of fever and used the method faithfully, or we may weigh the sum total of the experience of all who have written upon the subject. At first sight it may appear that the latter is by far the best course to pursue; but it must be borne in mind that the treatment is one opposed to the ordinary medical prejudices, that its efficient carrying out involves so much labor and attention as to be almost impossible to those who disbelieve in its usefulness, and that those physicians who claim most for the method affirm most strongly that to do much good it must be practised very vigorously and steadily.

These things being so, it seems wisest to look at the evidence from both points of view.

M. Franz Glénard affirms (*Glasgow Medical Journal*, 1874) that there have been from six thousand to eight thousand cases of typhoid fever treated by the use of cold in Austria, Prussia, and Russia, with an average mortality of from 4.5 to 7.6 per cent.; the previous mortality, under the old expectant method, having varied from 18 to 25 per cent. If these figures are correct, they are decisive. Where he gets them from, however, I do not know. All the evidence that I have met with is summarized in the following table. Unfortunately, it is not always easy to decide whether a German is writing about typhus or typhoid fever; but where it is not mentioned the probabilities are that the cases are in great part, if not wholly, enteric fever:

Table showing the Results of the Cold-Water Treatment in Typhus and Typhoid Fever.

NAME OF REPORTER.	PLACE.	NUMBER OF CASES.	MORTALITY, PER CENT.	REMARKS.
Jürgensen.	Kiel.	160	3.1	Previously 15.4 per cent. Typhoid fever.
Petri.	Laubbach.	31	3.2	
Liebermeister.	Basel.	1121	3.2	Previously 26 to 30 per cent. Treatment very rigorous. Typhoid fever.
Mosler.	Greifswald.	71	7	

NAME OF REPORTER.	PLACE.	NUMBER OF CASES.	MORTALITY, PER CENT.	REMARKS.
Mosler.	Greifswald.	92	9	Typhus exanthematicus, previously 50 (?) per cent.
Becher.	Ostpreussen.	17	24	Typhus exanthematicus, previously, on an average, 10 per cent.
Brandt.	Stettin.	187	2.1	Private practice.
"	"	84	10	Military Hospital. Previously 30 per cent.
Goden.	"	24	20.8	
Stohr.	Würzburg.	120	6.6	Previously over 20 per cent.
Drasche.	Vienna.	40	10	Year before 16.5 per cent.
Ziemssen.	Erlangen.	32	9.4	Formerly, with bad cases, 30.2 per cent.
Stieler.	Munich.	226	5.6	Formerly 12.15 per cent.
Pastau.	Breslau.	246	11.3	Typhus exanthematicus. Without baths, mortality 16.5 per cent.
Popper.	Prague.	20	5	
Riegel.	Würzburg.	156	4.4	Only serious cases included. Almost every fatal case came in too late for baths to do good.
Götz.	Prague.	54	5.5	Typhoid fever. Other cases treated at the same time, expectantly, 15.4 per cent.
"	"	50	18.8	Typhus exanthematicus.
Scholz.	Bremen.	125	4	Typhoid fever.
Wunderlich.	Leipsic.	155	7	Typhoid fever. Previously 18.1 per cent. out of 1178 cases.
Zaubzer.	Munich.	356	5.6	Typhoid fever. Previously 17.6 per cent. out of 701 cases.
Bauer.	"	87	7	Typhoid fever. Previously 11½ to 16 per cent.
Duchek.	Vienna.	60	28.3	According to Brandt, this high mortality depended upon the treatment having been imperfectly performed.
Krofft-Ebing.	Rastatt.	105	25.7	Only bad cases. Previous mortality 34 per cent.
Wille.	Rheinau.	59	19	
Stecher.	Claye.	146	8.2	
Schönheiden.	Dammartin.	82	3.6	Mild epidemic.
Pfeifer.	Weimar.	58	5.2	
Leube.	Ulm.	47	19	Typhoid fever, among French prisoners of war. Baths of moderate temperature used.
Böhm.	Niederbronn	131	11.5	Typhoid fever. Military hospital.
Gersauer.	Vigy.	97	6.18	Typhoid fever. Mortality on expectant treatment 23.91 per cent.
Drasche.	Vienna.	55	19	Typhus.
Merkel.	Nuremberg.	41	2.2	Typhus fever.
Loebel.	Vienna.	87	18.4	Typhoid fever.
"	"	105	28.6	Typhus fever. The treatment in this and in the preceding case was not thoroughly carried out; the patients mostly receiving only three baths a day.
Glénard.	Lyons.	52	0	Typhoid fever.
Schmidt.	Erlangen.	56	0.18	Several fatal cases not counted, because not received until the fifteenth day, and, therefore, too late to test the treatment; they bring the total mortality to 4.14 per cent.
Heubner.	Leipsic.	72	0.14	
Binz.	Versailles.	190	2.1	Soldiers. Mostly, if not all, typhoid fever.
Zeroni.	Mannheim.	72	18	Soldiers.
Valette.	Lyons.	21	0	Typhoid fever.

This table is of such a character that any lengthy discussion of it seems unnecessary. It is, however, allowable to call attention to the facts that the failure of the method at Vienna is, by the upholders of it, very

justly attributed to the inefficient carrying out of it, and that in some other instances the apparent high mortality is due to none but the most serious cases being included, or to the patients having been soldiers, worn out by the hardships and toils of a severe campaign.

When the evidence furnished by single observers is noted, the results are even more astonishing than that of the above table; so that although the aphorism of Brandt, as quoted and endorsed by Glénard,—“every enteric patient regularly treated from the commencement by cold water will be free from complications, and will recover,”—can scarcely be accepted, yet the great merit of the method cannot be gainsaid.

Prof. Liebermeister has employed the cold-water treatment on a larger scale than has any other individual. At the hospital at Basel, up to the year 1865, 1718 cases of typhoid fever were treated upon the expectant plan, with a mortality of 27.3 per cent. In 1865, Dr. Liebermeister introduced the use of cold bathing in a timid, inefficient manner, and reduced the mortality, in 982 patients treated, to 16.2 per cent. In 1866 he commenced the vigorous regular employment of the method, and reduced the death-rate, in 1121 patients treated, to 8.2 per cent. Prof. Liebermeister himself criticises very closely, in the recent *Encyclopedia of Medicine*, these statistics, and raises the mortality, by excluding trifling cases, to from 10 to 11 per cent.; but, after the anti-pyretic treatment has been even unjustly dealt with, the statistics still show that the mortality under the cold-water treatment is not half what it formerly was. Further, a certain proportion of cases are always admitted to the hospital moribund, too late for any human agency to be of avail: these cases, of course, maintain the same proportion under any treatment; they really constitute a large part of the deaths seen in the cold-water treatment, so that if they were eliminated from both sides the death-rate “under the anti-pyretic plan would be but a small fraction of what it would be under the other.”

In hospital practice the patients are very rarely received upon the first day of the attack, and very frequently do not enter the wards until the third week, so that the statistics which are included in the above table, or those given by Prof. Liebermeister, favorable as they are to the new treatment, only express a portion of the truth. If the good effected be so great when the remedy is often not applied until the second or third week, much more is to be expected when it is employed faithfully from the moment the temperature becomes elevated.

Accordingly, Brandt is said to claim that if the case be properly treated, from the onset of typhoid fever, death will never occur; and it is stated (London *Lancet*, January 23, 1875) that out of 259 cases he has had 259 recoveries. I have not had access to the original papers of Dr. Brandt, and cannot, therefore, analyze his statistics; but Glénard (*loc. cit.*) is just as enthusiastic; he states, “You will not find in the five or six thousand cases of typhoid fever treated by this method one single unsuccess among those which have been submitted to it since the beginning of the disease.”

It is not necessary to endorse this statement as absolutely true in order to accept the proposition that the extreme value of systematic cold bathing in typhoid and typhus fever has been so abundantly demonstrated that no excuse remains for the further neglect by physicians of this most important measure. The immediate effects of the bath upon the symptoms of the disease and upon its duration will be considered in the next article.

H. C. W.

CORRESPONDENCE.

LEIPSIC, January 16, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Last evening, January 15, Dr. Angelo Mosso, of Turin, delivered an address before the Physiological Society here, upon “A New Method for Measuring the Alterations in the Dimensions of Blood-vessels in the Living Man;” an abstract of which I send you, as I am sure that the attention and interest of many of your readers will be excited by it.

Dr. Mosso was last year occupied in observing the alterations in the size of certain organs, such as the kidney, which take place when, after their removal from the body, an artificial circulation is brought about in them. To this end he made use of a vessel with three tubulatures. In this the organ under examination was placed, and while two of the apertures allowed the ingress and escape of the circulating fluid, in the third was inserted an upright tube which would show the expansion and contraction of the organ through the medium of oil or water, with which the vessel was filled, and which rose or fell in the perpendicular tube.

This method of marking the expansion was attended by the drawback, that an increase in the height of the column in the tube exerted a perceptible pressure upon the expanding organ; and to avoid this he constructed an apparatus which he has since been able, with remarkable success, to turn to advantage in his investigations and experiments upon the living man.

This apparatus, which Dr. Mosso has named plethysmograph, consists of two distinct portions: one, by means of which the change in volume of the extremity under examination can be transformed into a measurable motion; the other, serving to record this motion without in any way influencing the pressure upon the surface of such extremity.

The first is a tin vessel large enough to receive the fore-arm comfortably (it can, of course, be made of a proper size for leg or thigh), armed with two tubulatures and closed near the elbow by an india-rubber ring, which effectually prevents the escape of the water with which it is to be filled. One of the tubulatures is at the end, and is connected with a flexible tube which runs to the graphic portion of the apparatus, and the other, on the upper side, is used to fill the case completely with water. In it a thermometer is usually inserted through the cork which closes the case completely. The tube

from the distal end is conducted, as nearly level as possible, to what may be termed a glass bucket, which hangs exactly counterpoised in a mixture of alcohol and water, from a ribbon running over a pulley. To the other end of the ribbon is attached the pen which is to trace the expected curve upon a rotating drum.

The arm having been introduced, and its owner placed in a comfortable sitting position, the case is completely filled with water, as is also the tube which runs from it. Enough water is also in the bucket to cover the end of this tube.

If now the volume of the enclosed extremity increases from any cause, water is pressed out of the case through the tube into the bucket, which becomes heavier and descends, thereby causing a motion of the pen in an upward direction. If, on the other hand, the volume of the extremity diminishes, then the water in the bucket is driven back to the case by atmospheric pressure, and, the bucket itself rising, a motion in the opposite direction is communicated to the pen.

The various difficulties which arose in the path of the inventor of this apparatus, not the least of which were the fact that the bucket underwent a progressive loss of weight as it descended into the fluid under it, and the necessity of providing against an overflow from the necessarily small bucket in case the extremity expanded very much, have been most ingeniously surmounted, and the apparatus as exhibited last night before the Society worked admirably, as it has done during other experiments which I have witnessed.

Besides exhibiting his apparatus, from my necessarily imperfect description of which I trust some idea may be gained, Dr. Mosso showed a number of tracings taken under different circumstances, and from these and his remarks it seemed plain that he had devised a means for studying the increase in volume of the blood-vessels of the extremities, and, through observations upon these, of gaining information with regard to the condition of the blood-vessels of the brain,—information of value not only from a physiological stand-point, but also in the solution of some questions in experimental pharmacology, and perhaps in clinical medicine. In passing, it is worth while mentioning that Prof. Wunderlich, who was present last evening, has already taken steps towards some investigations with the instrument in the hospital.

The tracing obtained from a man who sits perfectly quiet, and with his mind in as placid a condition as possible, is, so to speak, a straight line, varied at regular intervals by the respiration, and at irregular intervals by certain unexplained and small changes of volume which are not coincident in both arms. The latter are termed “spontaneous” movements, and both are readily allowed for in observing the curves, as they present distinctive appearances.*

When, now, the apparatus is in working order, the blood-vessels are observed to change their volume in the most remarkable and hitherto unsuspected manner.

Volatile substances, as ammonia, held under the nose for a moment, as well as touching the other hand with a piece of ice, caused a decided alteration in the amount of water in the case. In each instance the volume of the arm decreased. Besides these phenomena which were shown, Dr. Mosso showed the tracings and described some of the phenomena which showed themselves when the subject of the experiments was Dr. Pagliani, a friend who on several occasions submitted himself to what must certainly be a somewhat wearisome process.

In Pagliani's case, a cup of coffee was sufficient to cause a decided contraction of the blood-vessels of the arm, which lasted for three-quarters of an hour, while, on the other hand, on one occasion, while he slept the arm increased very greatly in volume, and the “spontaneous movements” were much greater.

During this sleep, the barking of a dog, the striking of the clock, and a slight touch upon the cheek, caused a temporary, but not complete, reduction of volume. On waking, Pagliani remembered nothing of the sounds or the touch. Before his waking the vessels again contracted, and when he was fully conscious they had resumed their original condition. The speaker drew from this and another similar experiment the conclusion that consciousness is only possible when the blood-vessels contract strongly, and the blood streams from the periphery to the centre.

On one occasion, when Dr. Pagliani was perfectly quiescent, the sudden though quiet entrance of Prof. Ludwig caused a most marked contraction of the blood-vessels of the arm; and indeed when Mosso himself or others of the students in the Physiological Institute were the subjects of experiment, this same contraction took place, showing, as the lecturer said, when one considers the close and friendly, one might almost venture to say familiar, relation in which Prof. Ludwig stands to his pupils (thereby eliminating alarm or uneasiness from the question), with what veneration and respect he was regarded by them, as in silence their very blood-vessels drew together to do him honor.

Invariably it has been found that the slightest mental effort is accompanied by a reduction in the volume of the arm; a comparatively simple sum in multiplication producing a very marked effect.

In connection with this point, Dr. Mosso related a story of his experience in Turin with a friend of a literary turn and a good classical scholar. The latter entered his room while he was occupied over his apparatus, and asked of what possible use such an affair could be. “It will tell whether you are as well up in Greek as in Latin,” replied Mosso, and thereupon, copying off a page of Latin and one of Greek, he put his unfortunate friend into the machine, and asked him to read both pages. The Latin came first, and the arm-volume remained stationary; but when the Greek was begun there was a sudden and great alteration, the arm-volume diminishing.

As may be imagined, the address was exceedingly interesting; and it is a matter for congratulation that

* The pulse also makes a slight impression.

Dr. Mosso is still prosecuting his investigations, which it is to be hoped will finally see light in an extended and complete form. I should not omit to say that the alterations caused by muscular contraction are only avoided through the intelligence of those upon whom the experiments are made; but it is quite safe to "stigmatize" those who have been the subjects here, as Helmholtz did his friends, as persons of perhaps more than ordinary intelligence; besides, the alterations of volume from muscular movements can be readily recognized, and the experiment repeated or allowance made for the error.

Dr. Mosso's address was attentively listened to, and warmly received. He mentioned many experiments with various drugs; among others, one with nitrite of amyl, when there was a slow but perceptible contraction[?] of the vessels. This, however, and other similar observations, he will be able, he trusts, to work up more fully later. In this hope he is supported by those whom he yesterday addressed, all of whom seemed convinced that the new plethysmograph will be found a valuable aid to scientific research, especially in the hands of so careful an investigator as its inventor.

H. B. HARE.

AMERICAN MEDICAL ASSOCIATION.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

THE object of this communication is to call attention to the American Medical Association, whose twenty-sixth annual meeting will take place at Louisville, Kentucky, on the first Tuesday of May next. Instituted in 1847, through the influence and exertion mainly of one man,—Prof. Davis, then of Binghamton, and now of Chicago,—the Association has had, if not a brilliant career, certainly a very satisfactory one, despite the numerous attempts, private and public, which have been made from time to time to disparage and dishonor it. I express this conviction without the slightest fear of successful contradiction; for I profess to have some knowledge of its history, of its proceedings and transactions, and of the men who have been connected with it, either as members or officers. Of the latter there is a long list of names of which any medical association might well be proud; men who have illustrated their profession by their labors and writings, and have added lustre to their age and country. The meetings have been, for the most part, well attended. During its session in this city in 1872, nearly eight hundred delegates were present; and last June, at Detroit, there were upwards of five hundred, and it is perfectly certain that if a more central point had been selected, the number would have been much larger. As it was, there were very few delegates from the Eastern, Middle, and Northern States. Nevertheless, the meeting was a highly respectable one, not only in relation to members but also in regard to talent, learning, and scientific attainments. What more especially impressed me was the great number of elderly, gray-headed men present on the occasion, men who had come from great dis-

tances to take an active part in the proceedings of the Association and to show their interest in its welfare and prosperity. Another circumstance which could not fail to strike every spectator was the decorum which characterized the proceedings of the meeting. The sections accomplished a great deal of work, and the discussions in most, if not all of them, were animated and interesting. As respects the social aspect of the meeting, nothing could have been more gratifying. The citizens of Detroit literally vied with one another to make the occasion one of high social enjoyment. Their hospitality was absolutely unbounded, and will long be remembered by every member of the Association.

In the face of all these facts, I was not a little surprised last summer when I saw an editorial statement in the *Times* that the meeting had been a failure, inasmuch as, it was alleged, it did not represent the American medical profession, owing to the absence of many of its best and most distinguished members. This, it seems to me, is begging the question. No rational person would expect that all the most prominent members of the profession would attend every meeting. Philadelphia, Baltimore, New York, and Boston, for example, were all poorly represented. Many of the great lights in all those cities were absent; and you, yourself, remained away, snugly ensconced behind your editorial tripod, or, it may be, engaged upon some experiment intended to elucidate some obscure point in the physiology of the nervous system, or the action of some article of the *materia medica*. Why the meeting at Detroit should be denounced because of the absence of those lights passes understanding. Did those men remain away because they felt indifferent respecting the success of the meeting? Was it because they dreaded a journey of six, seven, or eight hundred miles in the heat and dust of summer? Finally, was it because the physicians of the Eastern, Northern, and Middle States supposed they might lose some of their effulgence by contact with the Western and Southwestern members of the profession? Whatever the cause may have been, it reflects no credit upon those sections of the country that they permitted their representative men—*those great lights* of the profession, as you regard them—to remain at home, while their more humble but more active and industrious brethren of the great West were zealously laboring and spending their time and money in upholding an Association which, to say the least of it, has done more in harmonizing, unifying, and socializing the medical profession of this country than all the medical societies, great and small, civic and rural, that have ever been formed on this continent. Taking this view of the subject,—and no unprejudiced man acquainted with it can look upon it in any other light,—is it not our solemn duty to sustain the Association, instead of decrying and undermining it by insinuations of failure, if not actual abuse for any of its short-comings? The old adage, "Give a dog a bad name and you might as well hang him," has a powerful significance here. Some men—certain editors in particular—think it their duty to disparage everything Ameri-

can, and they consider themselves supernally happy if in instituting comparisons between the physicians and institutions of this and other countries, they can push us into the gutter. With such growlers I have no sympathy; and in saying this it is far from my wish to be understood as being blind to our manifold sins of omission and commission. No man, perhaps, feels more sensitive upon this subject than I do. As a teacher for forty years in prominent medical schools, and as a man who has seen much of his profession, I am free to confess that we have much to be ashamed of; and yet, despite this averment, I experience a sincere pride when I reflect that I am an American physician and surgeon; for I ask myself the question, What country on the face of the earth has ever done so much in so short a time in developing its medical profession as my own? What nation has ever produced so many great physicians, surgeons, obstetricians, teachers, authors, and scientists as ours, and in so brief a period?

These reflections bring me back once more to the special object of this communication. The American Medical Association has existed as an active body for a quarter of a century, and now numbers nearly five thousand members, including many of the most distinguished and earnest workers in the profession. Its next meeting is to take place at Louisville, Kentucky, a State which has produced McDowell, the father of ovariotomy; Dudley, the great lithotomist; Short, the learned botanist; Miller, the able obstetrician; and a host of excellent teachers and practitioners equal to any similar number of men in the country. A residence of sixteen years in Kentucky, and an extensive acquaintance with its citizens, afford me the assurance that the Association will meet with a most cordial welcome at Louisville; and to make the meeting a success, or, in other words, what it should be, it is only necessary that the great lights of the profession who absented themselves from the meeting at Detroit should turn out in full force next May. I appeal to the common sense of the profession whether this would not be a much wiser and better plan than to indulge in disparaging remarks, not only in bad taste, nay, let me say, the worst possible taste, but calculated, when seen abroad, to lower us in the estimation of our European brethren, and to humble our national pride.

At the meeting in this city, two years ago, I offered a resolution looking to a radical change in the character of some of our proceedings. I refer to the substitution of addresses in medicine, surgery, and obstetrics for the meaningless reports upon these topics to which the Association was annually obliged to listen, at the expense of much of its time and the annoyance of its patience. At the meeting at St. Louis in 1873, the plan suggested in the resolution was substantially adopted; and yet the address in medicine delivered at Detroit last June was simply a report of the contributions made to our periodical literature the year previously; or, in other words, a summary of some of the leading practical facts developed during the last twelve months. All this would be well enough, if we had not several medical journals the

avowed object of which is to furnish the reader with just such matter. What the Association needs is elaborate, learned, and well-digested addresses in each of these branches of medicine, upon any subject the writer may select, using every effort to make this discourse at once attractive, fresh, and truly instructive. The rule provides that the reading of each paper shall not exceed forty minutes. This is simply absurd, and, therefore, the sooner it is abolished the better.

Much abuse has been heaped upon the Transactions of the Association, of which twenty-five portly volumes have now been issued. That these volumes contain a good deal of rubbish is unquestionable; but it is equally true that they comprise many papers of great value, abounding in excellent material and in finished scholarship. The British Medical Association, now in the forty-third year of its existence, has no such record; and, judging from what I witnessed at two of its meetings, I am bound to declare that our proceedings compare most favorably with those of that famous institution.

I have the honor to be, very respectfully, yours,

S. D. GROSS.

PHILADELPHIA, February 1, 1875.

PROCEEDINGS OF SOCIETIES.

NEW YORK ACADEMY OF MEDICINE.

STATED MEETING, FEBRUARY 4, 1875.

THE subject for the evening was pneumonia, its etiology, treatment, etc., and Dr. AUSTIN FLINT was called upon to open the discussion. He said he was not prepared to enter upon an elaborate discussion of the subject assigned him, but would simply indicate some of the points of inquiry that suggested themselves to his mind.

First, he would refer to the diversities which disease presented at different times and places. Our medical progenitors attached more importance to this aspect of disease than we do at the present day. Perhaps the present tendency to accept nothing that cannot be accounted for or explained may have an influence. The disease under consideration this evening, for example, presents great diversity. Pneumonia is a disease which, ordinarily, is attended with no danger to life, yet at certain times and places it assumes a character which renders it one of the most fatal of affections. So in regard to scarlet fever and other diseases.

In the second place, the complications of disease, we find, with our present knowledge, great difficulty in explaining. Whether they are due to differences in degree of the initiatory cause, or to differences in regard to the susceptibility of the system, we cannot easily determine.

Does pneumonia at the present time, as it prevails in this city, present any unusual complications? He, in connection with this inquiry, gave a brief account of three cases which came under his observation within the past month. The first case is that of a young man, aged 30, whom he saw with Dr. Caro on June 18. A few days prior to this date, he was attacked with great pain in side, with high febrile movement, but the doctor could not make out any of the physical signs of pneumonia. Dr. Flint was also unable to discover any of the physical signs of pneumonia at the first consultation. He saw this patient again January 20, and at that

time the lower lobe of the right lung presented well-marked crepitant râles, the febrile movement high, but less than it had been a few days before. On the 21st, he was delirious, but there were no signs of pericarditis. He did not see this patient after this date. He was seen by Prof. Clark. Death took place January 23. The next case was that of a young man, aged 30, of good habits, whom he saw with Dr. Keyes, January 31. The patient presented the signs of pneumonia, with partial solidification of the lower lobe of the right lung. He had high febrile movement, but there was nothing in the case to denote any immediate danger. He met Dr. Keyes a few days afterwards, who said the patient was doing well. On the 25th, he received a note from Dr. K., stating that this patient became violently delirious and died before morning.

The third case was in the person of a woman, 68 years of age, who was seen January 31. She had been attacked three or four days before, and had solidification of the lower lobe of the right lung, and some signs of the same at a point in lower lobe of left lung; the pulse and temperature were not inconsistent with a mild form of pneumonia. This patient died during the night.

Without stopping to follow up the inquiries which these cases suggest, Dr. Flint passed on to the consideration of the different forms of treatment of pneumonia. Statistics do not give very satisfactory results in regard to the advantages or disadvantages of bleeding. He has regarded opium as an important measure of treatment, especially in cases characterized by vigilance, restlessness, and perhaps delirium.

Dr. WM. H. THOMSON made some remarks with reference to the use of cold in the treatment of pneumonia, and read the following report of cases in his charge in Bellevue Hospital during the past month:

Case I.—W. F., native of Germany, aged 40, upholsterer; mother died of phthisis, otherwise family history good; is a moderate drinker, but not often drunk; has had rheumatism and diphtheria; never had malaria.

Nine days before admission, while working out of doors and perspiring, and subsequently becoming chilled, was seized with chill and rigor, and had pains all through his body. Had another chill six days before admission, with acute pain in his right side, under nipple.

January 8.—On admission, patient has high febrile movement; pulse 105; respiration 32; temperature $103\frac{1}{2}^{\circ}$; surface of body hot and dry; tongue coated yellowish; lips parched, great thirst; marked dulness over right lung, below spine of scapula; broncho-vesicular breathing at upper part; crepitant râles. Ordered ammon. carb., gr. x, quin. sulph., gr. ii, every two hours. Also two pounds of ice in bag to chest.

January 9, 2 A.M.—Temperature 100° ; ice removed. 5 P.M.—Pulse 98; respiration 28; temperature $102\frac{1}{2}^{\circ}$. Ordered ice to chest, and treatment continued. 9 P.M.—Temperature 100° ; ice removed; feels easy and inclined to sleep.

January 10, 10 A.M.—Patient passed a good night, and is feeling comfortable this morning. Temperature 99° ; surface of body warm and moist; bowels confined; but little pain in side; less sputa. Ordered pil. cath. co. No. 3; the same treatment continued, excepting the ice.

January 11.—Patient feels very well. Temperature 99° ; respiration but little accelerated; pulse regular and of good volume. Resolution progressing. From this date patient rapidly improved, and was discharged, cured, on the 18th.

Case II.—D. C., aged 32, Ireland, laborer; general health good, temperate. One week before admission, while selling books on street-cars, was seized with chill and rigor, with pain in left side, compelling him to cry out. He went home and took to his bed.

January 8.—On admission, patient complains of weak-

ness and loss of appetite. Has no pain in side, but little dyspnoea. Pulse 106; respiration 36; temperature 103° . Tongue coated, lips parched, bowels confined, urine scanty and high-colored. Complete dulness over left lung as high as angle of scapula; slight increase of fremitus, bronchial breathing, crepitant and subcrepitant râles. Ordered am. carb., gr. x, quin. sulph., gr. ii, every two hours, and oz. viii of wine, also two bottles of porter. At 5 P.M., temperature 103° ; ice-bag to chest. At 9 P.M., temperature $101\frac{1}{2}^{\circ}$; at 12 M., temperature 100° . Ice removed.

January 9, 10 A.M.—Pulse 80; respiration 24; temperature $99\frac{1}{2}^{\circ}$; feels well; treatment continued, excepting ice. 5 P.M., patient has slight headache; skin hot and dry; temperature 103° . Ordered two pounds of ice in bag to chest. 8 P.M., temperature 102° .

January 10, 1 A.M.—Temperature 100° . Ice having been on eight hours, is now removed. 10 A.M., feels comfortable, except has pain in affected side, which he says is sore and stiff, and interferes with his breathing. Ordered cups iii to chest, over left lower lobe. Temperature normal; treatment continued.

January 11.—Condition is improving, but pain is still considerable. Pleuritic friction heard at point of pain. Temperature 99° . Ordered cups repeated.

January 12.—Patient convalescent.

January 16.—Patient discharged, cured.

Case III.—E. W., aged 39, England, seaman; general health good; had typhoid fever eight months ago. During last twenty years has been a periodical imbibor; was on a spree two weeks previous to present attack.

Five days before admission, was attacked with severe chill and rigor, cough, and pain in left side, under nipple, and behind, over lower lobe. Remained in bed a day and a half, then got up. Had another chill, and pain in side of greater intensity, which compelled him to take to his bed, where he remained until admission, three days afterwards.

On admission, January 8, patient suffers from pain in left side, with hurried superficial respiration. Pulse 120; respiration 44; temperature 105° . Face flushed and hot, tongue dry and coated brown in centre, lips parched, great thirst, surface of body hot and dry, urine high-colored and scanty. Has an anxious expression of countenance. Physical examination shows over left lower lobe, behind, dulness, increased fremitus, bronchial respiration. Crepitant and subcrepitant râles. Exaggerated sounds over upper lobe, and opposite lung. 5 P.M., ordered ammon. carb., gr. x, quin. sulph., gr. ii, every two hours, also sponged down for twenty minutes. Ice-bag applied to chest during the night. Whisky, oz. i, every hour.

January 9, 2 A.M.—Temperature 101° ; ice removed. 10.30 A.M., pulse 108; respiration 36; temperature 104° . Passed a pretty comfortable night; slept several hours. P.M., ice re-applied. 4.30 P.M., temperature 103° ; pulse 104; respiration 40. 9 P.M., temperature 101° ; ice having given out, ordered cold pack. 11 P.M., temperature 100° .

January 10, 10 A.M.—Pulse 108; respiration 30; temperature 101° . Spent a restless night; somewhat delirious; is now easier, and inclined to sleep; no pain, and but little dyspnoea. Ordered stimulating enema, as bowels are confined.

January 11, 10 A.M.—Pulse 92; respiration 32; temperature 101° ; is very weak; had active delirium last night; enema caused two passages. Is now in cold perspiration; sleeping, with loud stertorous breathing and prolonged expiration; breathing interrupted; has subsultus tendinum; hard cough; sputa brown. Treatment continued.

January 12, 10 A.M.—Patient worse; pneumonia extended to right lung, upper lobe, also to left upper lobe. Breathes hurriedly; somewhat cyanosed; is stupid and

restless; subsultus continues, with carphologia. Ordered cups to left side. 4 P.M., pulse 104; respiration 38; temperature 104°.

January 13, A.M.—Typhoid symptoms prominent. Ordered ice to chest, and treatment continued. 12 M., temperature 101°; ice removed. Feels better now.

January 14.—This A.M. patient is delirious and very weak. Pulse feeble and intermittent; eats nothing. Temperature 100½°; pulse 116; respiration 30. 7 P.M., patient died.

Case IV.—R. H., aged 31, Ireland, domestic. General health good. Three days before admission, was seized with chills, irregular, and followed by sweating at night.

On admission, January 9, patient was suffering from great febrile movement; pain in left side at apex of lung; repeated epistaxis from left nostril. Temperature 103½°; pulse 104; respiration 28. No pneumonic sputa; cough slight and dry.

January 10, 9.15 A.M.—Pulse 100; respiration 30; temperature 102¾°. Restless; severe pain in chest; surface hot and dry. Ordered ammon. carb., gr. x, quin. sulph., gr. ii, every two hours. 4 P.M., pulse 108; respiration 40; temperature 104¼°. Ordered ice-bag to chest. 9 P.M., temperature 102°. 11 P.M., temperature 100°. Ice removed.

January 11, A.M.—Pulse 104; respiration 30; temperature 102¾°. Patient feels better. 5 P.M., pulse 108; respiration 36; temperature 104¼°. Ordered ice to chest. 9 P.M., temperature 97½°. Ice removed; treatment continued.

January 12, 10 A.M.—Patient much better; no pneumonic sputa; pain almost disappeared. Temperature 103½°. Ordered ice to chest. 2.30 P.M., temperature 101°. Ice removed.

January 13.—Patient feels comfortable. Same treatment continued, ice being applied when temperature above 100°.

January 14.—Temperature normal, and patient gradually improving, and from this date rapidly convalesced.

Case V.—R. E., aged 32, boatman, admitted January 26, 1875. Family history unimportant; has always had good health; drinks, but not habitually. One week before admission, got his feet wet, and was shortly afterwards seized with vomiting and purging; had no pain at any point, no fever until three days after attack. On admission, patient is very feeble, has excessive diarrhoea, yellowish discharge; pulse weak, full, and soft, 100. Respirations accelerated, forty per minute; temperature 103½°. Is slightly delirious, talks incoherently; has considerable cough, but slight expectoration. Tongue coated brown, lips parched, and surface of body hot and dry. In front, has broncho-vesicular breathing; behind, ordinary signs of pneumonia over middle and upper lobes of right side.

Ordered carb. ammon., gr. x, and quin. sulph., gr. ii, every two hours, with extra diet, and oz. vi whisky per diem. Ice was ordered to chest at 6 P.M. Temperature 104°; pulse 124; respiration 30.

January 26, 2 A.M.—Temperature 100½°. Ice removed; patient states that he feels much better; pulse slower and of better volume, breathes more easily. 10 A.M.—Pulse 116; respiration 28; temperature 101°. Feels comfortable. 4.45 P.M.—Pulse 100; respiration 24; temperature 102½°; condition somewhat better. 6 P.M.—Temperature 103°; ordered ice to right chest. 12 M.—Temperature 100½°; patient comfortable, and dozing. Ice-bag removed.

January 28, 10 A.M.—Pulse 78; respiration 30; temperature 98½°. Slept soundly after removal of ice; bowels very loose, fæces still yellow. Patient is rational, and perspiring freely; pulse full, soft, and pretty good volume; tongue dry, and coated brown. Treatment, excepting ice, continued.

January 29, 10 A.M.—Pulse 70; respiration 28; temperature 97½°. Ordered bismuth, gr. xx, pepsin, gr. x, every three hours for three doses. Diarrhoea diminished; patient feeling well; no extension of pneumonic signs.

January 30, 10 A.M.—Pulse 84; respiration 26; temperature 97½°.

February 1, 10 A.M.—Patient feeling pretty well; no dyspnoea or pain at any point in chest; expectorates brownish sputa; pulse moderately strong, and but little accelerated. Physical examination shows subcrepitant râles over affected lobes. Treatment continued.

February 2.—Patient convalescent.

Case VI.—T. W., æt. 31, U.S., bricklayer, was admitted January 30, 1875, and treated precisely as the preceding cases, ice being used when temperature rose above 100°, and on February 4 pneumonia was resolving, and patient convalescent.

Dr. Thomson thought it was very important that physicians should keep reports of all cases they treat, both in hospital and private practice, and concluded by saying that he believed there were many men who had been in practice twenty years, and yet really had less experience than those who have had ten cases and studied them.

Dr. ALFRED L. LOOMIS: "We cannot treat pneumonia or any other disease unless we are familiar with the cause giving rise to its development. In pneumonia we have exciting and predisposing causes, and of all predisposing causes age is the most important. We rarely see this disease in young children; we see it most frequently between the ages of twenty and forty. The pneumonia we see in young children is bronchial pneumonia.

"We find also that climate has much to do as a predisposing cause of pneumonia. Those climates subject to sudden changes are more favorable to the production of pneumonia than those very high or very low.

"Intemperance and whatever interferes with health has very much to do with the development of pneumonia. My impression is that most cases of pneumonia met with are in persons who were not in good health before: hence I question very much that idiopathic pneumonia is frequently met with. If a man is charged with alcohol, for instance, and he places himself in a draught when heated, and gets pneumonia, is it an idiopathic pneumonia? It is alcoholic pneumonia. If a man under a malarial influence, as we all are in this city, exposes himself, and has pneumonia, it is not idiopathic pneumonia, it is malarial pneumonia.

"In regard to blood-letting in pneumonia, there are certain circumstances in which it is beneficial, but it would not be beneficial in a man suffering with malaria. We have two indications in the treatment of this disease: first, find its cause,—not the exciting cause, but the condition of the system preceding it. If the temperature is 104°, it is our duty to reduce it; if it does not rise above 103°, it is better to let it alone. The subject of cold as a means to reduce temperature has been ventilated; my own experience in regard to it, so far as it goes, is rather unfavorable. You can lower the temperature a degree or two by full doses of quinine, and I usually begin by giving gr. x, when the temperature is 105°. The second object in the treatment of pneumonia is to sustain the heart. So far as my experience goes, patients die from failure of the heart. As an agent to overcome heart-failure, alcohol is the remedy."

EXCISION OF THE BLADDER (*The Lancet*, January 9, 1875).—Dr. George Thomson reports a case of excision of the bladder occurring in a woman æt. 40, and following a fit of tenesmus brought on by acute cystitis. He believes the case to be unique.

REVIEWS AND BOOK NOTICES.

REPORT ON THE PROGRESS OF OTOLGY. By C. H. BURNETT and CLARENCE J. BLAKE, M.D. Boston, 1874.

We do not, as a rule, notice pamphlets, but this very handsome pamphlet of seventy-three pages is seemingly so thorough and complete that we call the attention of all interested in otology to it, as a whole library in a paper cover.

PHARMACOGRAPHIA. A HISTORY OF THE PRINCIPAL DRUGS OF VEGETABLE ORIGIN MET WITH IN GREAT BRITAIN AND BRITISH INDIA. By FRED. A. FLÜCKIGER, Professor in the University of Strasburg, and DANIEL HANBURY, F.R.S. London, Macmillan & Co.

This handsome volume of nearly seven hundred pages is a work upon materia medica proper, avoiding altogether pharmacy and therapeutics, and not diving too deeply into the chemistry of the subject. Its exact scope may be gathered from the following sentence, which we extract from the preface: "It is, in fact, a record of personal researches on the principal drugs derived from the vegetable kingdom, together with such results of an important character as have been obtained by the numerous workers on materia medica in Europe and America." The book is undoubtedly one of permanent value, containing an immense amount of facts, most of which have been verified by the personal knowledge of the authors. There are described in it a number of drugs, such as the Indian Ipecacuanha, which are never seen in this country, and some of which, we believe, have not found their way even into the United States Dispensatory. The descriptions of the various recent efforts at the cultivation of drugs, in England, in Europe, and in the Tropics, are exceedingly interesting. Altogether, the book will for many years be of great value to all interested in materia medica.

GLEANINGS FROM OUR EXCHANGES.

TEST OF DEATH.—Dr. Angelo Monteverdi states, as the result of a great number of experiments, that the subcutaneous injection of liquid ammonia produces invariably a vinous red spot, with very sensible projection of the hair-bulbs, while in real death these are as invariably absent.—*Arch. di Med., Chir. ed Igiene.*

REMARKABLE CASE OF FASTING (*Peninsular Journal of Medicine*, January, 1875).—Dr. A. A. Whitney reports a case of persistent fasting occurring in a man æt. 75, who for seven weeks took only about two ounces of solid food and a similar amount of liquid nourishment. There were periods of from ten to eighteen days when absolutely nothing but water and ice was taken.

He was suffering from religious melancholia, and made three unsuccessful attempts at suicide, but finally died from exhaustion produced by his voluntary starvation.

INFLAMMABLE GAS FOUND IN THE STOMACH (*Irish Hospital Gazette*, January 1, 1875).—Dr. Heynsius relates the case of a man who suffered violent eructations after eating, and on four occasions the gas which was discharged had caught fire, burning his lips and nose severely. He had symptoms of acid dyspepsia, with dilatation of the stomach, probably the result of a stricture of the pylorus. The vomited matter was examined, and the gas which it generated was found to consist chiefly of hydrogen and carbonic acid. In the distillate butyric acid was found, and the phenomenon was probably due to butyric acid fermentation, the hydrogen being the cause of the inflammability of the ejected gas.

FATTY DEGENERATION OF THE HEART IN ADVANCED LIFE (*The Lancet*, January 9, 1875).—Dr. L. H. Jayne believes feeble, irregular, or intermittent pulse, dyspeptic symptoms, epigastric pain, frequent vomiting, more especially after taking food, and diarrhoea, to be diagnostic of fatty degeneration of the heart in old people.

NOTES AND QUERIES.

1729 CHESTNUT STREET, February 13, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Early in March the buildings long known as the "Philadelphia School of Anatomy" will be destroyed for the new post-office. In response to a number of requests, I am endeavoring to gather the facts of its history for a concluding lecture. Many of the lecturers who have given courses in the two buildings are either personally unknown to me, or I may be ignorant even of the fact that they ever have lectured there at all. May I, therefore, take this method to ask them, through you, for all the information they can give me at once, either as to their own lectures or those of others, or in general any facts referring to its history? I want not only to be thus accurate as I can, but also to obtain many facts which must otherwise be lost. I would like to know not only the lecturers who have been connected with it, but also what work they did, whether literary, experimental, physiological, etc., while connected with it, for all this is a part of its history. Personal reminiscences, anecdotes, etc., I would be glad also to gather.

The lecture will be delivered in the Philadelphia School of Anatomy at 8 o'clock P.M., March 1, 1875, and I extend to the profession, and especially to those who have ever taught within its walls, a cordial invitation to be present.

Very truly, yours,

W. W. KEEN, M.D.

We have received a note from Dr. W. W. King, stating that in his letter to Mr. Fairthorne, published some weeks since in the *Philadelphia Medical Times*, it was inadvertently omitted that he employed chloral as an antiseptic as early as the latter part of 1871,—so far as his knowledge goes a year or more before the subject was noticed in the medical journals.

PROF. HARVEY L. BYRD, of Baltimore, has written us a letter containing a published card in regard to the resignation of Dr. W. W. Murray and himself from the College of Physicians and Surgeons of that city. The card is so long that we can hardly spare the space for it here. Our Baltimore correspondent supposed that the disagreement of the faculty was concerning the filling of certain chairs; but from the card it appears that the trouble grew out of this election indirectly. Dr. Murray says, "I resigned my professorship not because of the election or non-election of any one, but because I believe that I have, under cover of law, been deprived of a constitutional right or prerogative of which the Faculty had no moral right to deprive me."

PHILADELPHIA COUNTY MEDICAL SOCIETY.

THE next conversational meeting will be held at the hall of the College of Physicians, Wednesday, February 24, at 8 o'clock P.M.

Dr. James H. Hutchinson will read a paper on "The Use of the Ophthalmoscope as an Aid in the Diagnosis of Cerebral Disease."

The medical profession in the city are cordially invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM FEBRUARY 9, 1875, TO FEBRUARY 15, 1875, INCLUSIVE.

ROSE, GEORGE S., ASSISTANT-SURGEON.—Granted leave of absence for one month. S. O. 24, A. G. O., February 8, 1875.

SATURDAY, FEBRUARY 27, 1875.

ORIGINAL COMMUNICATIONS.

A FURTHER CRITICISM ON THE SO-CALLED CASE OF INFECTION BY SYPHILITIC SEMEN,

WITH REMARKS UPON THE TRANSMISSION OF SYPHILIS IN COITUS BY MEANS OF THE BLOOD, AND ITS BEARING UPON MARITAL RELATIONS.

BY R. W. TAYLOR, M.D.,

Surgeon to the New York Dispensary, Department of Venereal and Skin Diseases; Physician to Charity Hospital, New York.

IN the *Philadelphia Medical Times*, issue of February 6, 1875, I find a criticism, by my friend Dr. F. R. Sturgis, on a case reported by Dr. Isaac Smith, Jr., of Fall River, and published in the November number, 1874, of the *New York Medical Journal*. At the time of publication I read this case, and intended to criticise it in my forthcoming report on syphilis for the *Archives of Dermatology*; but, as Dr. Sturgis has brought it to the notice of the readers of this journal, I think that my remarks upon the case and my opinions of his criticism should be published in the same periodical. Thus far for preliminaries; now let us examine the case or premises. Briefly but correctly stated, this case is, as far as given by Dr. Smith, as follows:

A man has a chancre in February, 1872, which, existing eight weeks and then healing, leaves a cicatrix. Very soon he has secondary manifestations, showing that he is syphilitic. In a year he marries, and about six months after, his wife having prolapsus uteri, he notices a sore upon the os, which Dr. Smith considered a chancre. The history of the husband from the date of marriage to the discovery of the infection of his wife is not given, nor have we any circumstances relating to his coitus with her, nor of the peculiar conformation of his penis. In due time, secondary lesions show that the wife also is syphilitic. Virtually, the case ends here; but we have the further information from Dr. Smith, that in January the husband noticed another lesion on his penis, and upon this and the reporter's remarks or conclusions thereon, Dr. Sturgis makes some further criticisms. So that I shall have to consider in my review of this matter, first, the theory of syphilitic infection as advanced by Smith, and the criticism made by Sturgis; and, secondly, the views of both Smith and Sturgis as to the nature of the lesion on the penis which occurred in January, 1874. The latter consideration will be embraced in a subsequent paper.

As regards the woman's case, the question arises, What was the source of contagion, assuming, as we have every reason for doing, that she was virtuous, and that she contracted the disease from her husband? Owing, undoubtedly, to the fact that the husband did not present any lesions upon the penis, Dr. Smith thinks that the contagion was communicated through the semen; consequently, that it converts, in one particular, the view or law that the physiological secretions of syphilitic persons are

not capable of transmitting the disease. I shall not discuss here this question, but shall merely consider the bearing of the case upon it. As there was a chancre upon the uterus, it is absolutely certain that the point of entry of the syphilitic virus was in that organ, and that the active agent was the penis of the male. What, then, was the contaminating secretion? There is considerable evidence against the view that the semen was the cause; seeing that syphilitic men having no lesions upon their penis cohabit very frequently with females who do not become syphilitic. If we admit that the semen may convey syphilis, how can we explain the great number of cases in which women cohabit with syphilitic men with impunity? I have myself known of very many instances of this kind, but have not heard of syphilis having been communicated when no lesion or fissure existed on the male organ; indeed, if such a mode of contagion is possible, the number of women who would become syphilitic annually would be appalling. I purposely leave out of consideration at this time the question as to what effect the semen of a syphilitic man has upon the child and upon the health of the mother during the parturient period and afterwards. The fact that such multitudes of women escape points significantly to, and, I think, warrants, the conclusion that *the semen of a syphilitic man does not develop in the female the initial lesion of syphilis to be followed by general systemic infection*. Still, if we cannot reasonably explain that contagion in this case occurred through other secretions, we shall have to admit, though of course we do not believe it, that there is a probability of such contagion having taken place through the semen. I think that a very plausible and simple mode can be cited, and one which is borne out by well-established facts and by indubitable precedents. My friend Sturgis thinks—and I will first consider his views—that the infection took place through the secretions of urethral mucous patches, and so certain is he of this that he says, "Until the existence of this lesion in the canal, or upon the membrum virile, or upon any other part of the body capable of affording a means of contagion, be excluded, we are forced to render a verdict of *non-proven*." Again he says, "Are urethral mucous patches so extremely rare as to be entirely excluded as a probable means of contagion?" and, further, "Which in the present state of our knowledge is considered most unusual: the existence of mucous patches in the urethra, or direct infection by semen?" This explanation brings up some very important considerations,—namely, the question of the occurrence of mucous patches in the urethra, and of their greater or less rarity of occurrence. Certain it is that as their secretion is equally as contagious as that of the initial lesion of syphilis, had they existed in this case the contagion would have been, under the circumstances, inevitable. Some time ago my attention was prominently drawn to the lesions produced by syphilis in the urethral canal, and from the opinions which I gained by my study and observations of numerous cases I am now very much surprised at what is said by Sturgis

as to the existence of mucous patches in the urethra. As that canal is lined with a mucous membrane, it is of course liable to be the seat of the development of these lesions; yet it seems to escape in very many instances. It seems to enjoy an immunity similar to that of the conjunctiva. In a vast number of cases in public and private practice I have never been able to find this lesion, and several friends who see a large number of cases of syphilis have a like experience. I have sought for its description in various text-books and monographs, and yet it is not noted. Thus, Bassereau, in his classical treatise (*"Traité des Affections de la Peau symptomatiques de la Syphilis,"* page 318, Paris, 1852), gives a table of one hundred and thirty cases of mucous patches observed by him, and only one was at the meatus urinarius, while upon the prepuce and glans there were twenty-eight. I have seen an instance in which there was a mucous patch at the meatus, and one just inside the right nares. Other authorities are equally silent, and in the details of syphilitic cases in various works, monographs, and theses, though not treating of this subject, I have looked in vain for the statement that there were mucous patches in the urethra. I am somewhat surprised at this fact, seeing that the urethral mucous membrane, like any other, may be involved, in rare instances, by syphilis. Thus, in some rare cases, during the early secondary period patients express their surprise that they have what they call "clap." This occurs generally during or just at the evolution of the secondary lesions, and often at the time when the initial lesion is still active. Upon inspection, more or less tumefaction of the lips of the meatus is found, and a purulent discharge, sometimes quite copious, escapes. The symptoms are in some instances severe; in fact, the whole aspect of the case indicates urethritis. In some of these cases there has not been any anterior blennorrhagia, and in all of those I refer to there had been no recent coitus, all such having been rigidly excluded in which this act had been performed within a fortnight. The interesting point to be determined in these cases was, what was the nature and cause of the discharge? My studies have proved to me that a hyperæmia similar to that which invades the pharynx in early syphilis takes place, and that, owing to the conformation of the parts, the inflammatory process runs higher. In some instances, this hyperæmia begins spontaneously; in others, I have thought that previous attacks of blennorrhagia have, perhaps remotely, predisposed to it. According to my observation, this syphilitic urethritis, if we may so call it, is confined in point of time, as I have said, to the early part of the exanthematous period, sometimes being developed just before the time of the healing of the initial lesion. This condition is, singularly enough, passed over without description by authors generally, yet its existence is beyond doubt. My friend Dr. J. N. Hyde, of Chicago, is one of the few who have called attention to it, in a valuable paper upon syphilitic contagion, published in the *American Journal of the Medical Sciences* for January, 1874.

I have noted cases in which all sources of contagion were carefully eliminated, and in which this feature was observed. My interest in its study led me to examine three of my cases at various periods with the endoscope, and all that I saw was a swollen hyperæmic mucous membrane, secreting pus in great quantities, not differing in any particular from simple blennorrhagia. The inflammation extended to the proximal end of the fossa navicularis and slightly beyond; but there were no localized spots more inflamed than the rest; no evidence of any lesion like the mucous patch. Indeed, in one case I suspected the presence of the lesion, yet I did not find it, and my endoscopic examinations were very satisfactory. I am thus particular in describing at some length this affection, in consequence of the stand which I have taken as to the occurrence of mucous patches in the urethra. Besides this, I wish, in case of argument, to eliminate thoroughly and differentiate beforehand this condition, which might be quoted as being due to the presence of these mucous lesions, whereas I think that the facts which I give will prove fully that it does not depend upon them as a cause.

Now, then, though I am not prepared to deny that mucous patches may be developed in the urethra, I will state most positively that the probabilities of the occurrence of such an accident are among the most remote of any of the lesions of syphilis.* Indeed, as a clinical rarity it is one of the rarest; of course I mean well-defined typical mucous patches. Now, it is very certain that Dr. Smith's patient did not have the form of urethral syphilitic trouble which I have detailed, nor have we any evidence that there was the slightest abnormality of his canal. If he had had urethral mucous patches, I think that the sensations which they would have produced, and the secretion which would have escaped, which, however, might be so

* I am led to think from careful and extended study and reading that no author has really seen mucous patches in the male urethra, or has convinced himself conclusively that such have existed in any case. Unfortunately, there is such a want of precision of statement of several that their meaning can only be arrived at by inference, and by studying the data upon which they have based their assertions. I will endeavor to show the state of the question. Virchow (*Würzburger Verhandlungen*, vol. iii, 366) speaks of a case of ulceration of the membranous and prostatic parts of the urethra, involving also the bladder, which, he thinks, was of syphilitic origin. He also says that syphilitic ulcerations and cicatrices of the canal of the urethra are very common, and are similar to those of the larynx. Further, he adds that he has seen these lesions in the female urethra. Lancereaux (*Traité historique et pratique de la Syphilis*, Paris, 1873), in referring to this statement of Virchow, says that he can neither confirm nor invalidate it. Then we find that Rollet says (*Traité des Maladies vénériennes*, Paris, 1865), in speaking of the site of development of mucous patches, and referring to the urethra, "An observer has found examples of them even at a very great depth; I have never seen such." Again, we read in Bumstead's excellent work, "Mucous patches upon the genital organs in both sexes sometimes give rise to a discharge resembling gonorrhœa, from the neighboring mucous membrane," etc. It will be seen that the only really definite statements are those of Rollet and Lancereaux, who have not seen these lesions in this site. The reference of the former is, without doubt, to Virchow, whose case is so doubtful in all its particulars, both as to what the lesion really was, and whether it was truly of syphilitic origin, that it is not worthy of any consideration. It is evident that Virchow has assumed the occurrence of syphilitic lesions in the male urethra from the fact that he has seen such in that of the female. The statement made by Bumstead evidently refers to lesions outside of the canal, involving in the male either the prepuce or glans or both, and in the female the orifice of the urethra, for he says distinctly, "Mucous patches upon the genital organs," etc. Certainly, although the analogue in function, the female urethra, owing to its opening into the vulva, which is so prone to the development of mucous patches, cannot be classed with the male urethra as being equally susceptible to these lesions. So that, all things being considered, it will be seen that there is no positive statement that mucous patches have been found by any one in the male urethra, but there are such assertions that they have not been discovered there. The existence of a discharge does not prove that these lesions necessarily give rise to it.

slight as only to glue the lips together, would have caused him to fly to his physician, for he knew of his syphilitic condition, and showed a solicitude about himself by consulting Dr. Smith at each manifestation of mischief. Then, again, we have no evidence in this case that the mucous membranes were involved. It is fair to assume that if the patient had experienced any abnormal sensations in his mouth and throat he would have called the physician's attention to them, and that the latter certainly would not have failed to mention them among the other lesions which he speaks of. Thus, as he, perhaps, has no lesion of one mucous membrane, it is fair to think that the others escape. For, although not absolutely the rule, we very frequently see the mucous membranes of various parts involved at one time, showing a tendency in them generally to syphilitic action. Thus, in clinical practice, how often do we find buccal mucous patches co-exist with similar lesions about the genitals! While, therefore, we cannot lay this coincidence down as a law, yet it is of frequent occurrence. I should add further that it can much more frequently be noticed that buccal mucous patches exist alone while other mucous membranes escape, than that the latter are involved while the mouth escapes. Thus, in by far the greater number of cases, if mucous patches exist upon the genitalia, it will be found that the mouth also has been attacked. Other observers have undoubtedly noticed these peculiarities of distribution. The practical deduction of these points is this, that it is very probable that had mucous patches existed in this man's urethra, that mucous membrane would not have been the only one involved, and that the mouth would almost certainly have been attacked.

Now, then, in fairness to Dr. Sturgis, I must state his reasons why he accounts for the contagion by the presence of mucous patches in the urethra. To quote his words: "But perhaps it may be asked, Why suspect the presence of mucous patches? For three reasons: first, because they are the most common lesion of the earlier manifestations in syphilis; second, because they are often overlooked or misunderstood when seated upon the mucous membrane of the penis, or in the urethra; and, third, because it is more than probable that the man had one within six months after infecting his wife." We certainly grant that, owing to their frequency of relapse, mucous patches are more often met with than lesions of the skin. Still, we must add that there are certain membranes which, by the experience of all observers, are shown to be more liable than others both to this development and relapse, and that there are other membranes which are rarely if ever attacked. The urethral mucous membrane belongs to the latter class: therefore I think I need not refute this statement any further. But I must consider the third reason given by Sturgis, who thinks that the lesion on the penis of the husband which showed itself six months after the wife's infection was a mucous patch, consequently that he might have had a similar lesion inside of the canal just at the time when he infected his wife. I am prepared to admit that perhaps this lesion was a mu-

cous patch, as we sometimes, though very seldom, see them *there*, namely, at the lips of the meatus; yet I do not think that the inference is warranted. I have, I think, shown that there was no reason for suspecting any intra-urethral lesion, as the symptoms of it are not given at all.

And again, we have no evidence proving that any mucous membrane of the body was involved. From all of these considerations I am forced to the conclusion that the chancre on the uterus of this woman was not produced by the secretion of mucous patches hidden in the urethra of her husband. The fact that the organ involved was the uterus, and that the husband did not have buccal lesions, is sufficiently convincing that contagion by bestial practices did not occur.

As the question involved in this case is so interesting to science and so vitally important to hygiene, I think I need offer no apology for my somewhat extended review of it.

The view that the contagion was not by means of urethral mucous patches being then considered unproven, what is the most probable source? As the urine is known to be perfectly innocuous, the only other fluid is the blood. Was this contagion effected through the blood? I certainly need not at this late day argue the question of the contagiousness of this fluid. The experiments of Pellizari and numerous clinical cases have demonstrated this, so that now it is an admitted fact. Let me quote from the veteran syphilographer Waller, of Prague, who did so much in establishing the fact of the contagiousness of the secondary lesions of syphilis and of the blood in face of the witticisms and biting sarcasms of Ricord, who then denied such a possibility, though he was afterwards convinced of his error by the experiments of his own pupils. Waller details the case (*Prager Vierteljahrsschrift*, vol. xxix., 1851) of "a man who became syphilitic in December, 1848. He had angina and syphilitic iritis, and seemed to be entirely cured at the end of the following June. Towards the close of the year 1849, he married a perfectly healthy girl. In the honeymoon the coitus was guardedly indulged in, by reason of the pain it produced in the woman, who had previously never had any intercourse with men. At the end of December both man and wife had a slight flow of blood during the act, and in January, 1850, the woman noticed a macular and squamous syphilide over the whole body, and a little later, condylomata appeared on the pudenda. The man neither then nor thereafter showed any evidence of the disease." I have no doubt that this case suggested to Pellizari the idea of the experimental inoculations which he so successfully made.

Within the last few years, Maurice, in his interesting work (*"Mémoire sur les Affections syphilitiques du Système osseux,"* Paris, 1872), incidentally reported a suggestive and conclusive case which is well worthy of being reproduced here in brief. During the siege of Paris, towards the end of the year 1870, a man, whose wife had for safety been sent into the country, contracted a syphilitic chancre, which was duly followed by general manifestations. Under treatment, all traces of the disease had disappeared at the time

of the return of his wife, which was near the end of February. Maurice states that he warned him beforehand of the various dangers of contagion, especially of that of the blood. Three days after the wife's return, the husband went to Maurice in great alarm, and told him that in sexual intercourse he had become chafed, and that blood had escaped. Upon examination of his wife, three weeks later, a chancre was found at the orifice of the vagina, and in due time she presented evidences of syphilis.

Here, then, are examples of an occurrence which I do not think is rare. There are points of resemblance between them and Dr. Smith's case, though in the latter the flow of blood is not mentioned. This, however, may be readily explained. Since the semen is powerless in conveying syphilis, is it not in perfect accordance with the laws of syphilitic contagion and of well-established precedents to suppose that infection occurred in Smith's case through the blood? The circumstances are favorable to that view. The husband is undoubtedly syphilitic. His wife's uterus is in a morbid condition, and falls downwards. Then; again, though very susceptible to the transudation of fluids in the normal state,—owing to its great vascularity and to the superficial position of its capillaries,—is not a uterus which is inflamed and perhaps eroded of its mucous membrane still more susceptible? Certainly there could be no soil more permeable to the syphilitic virus. As I have said, there is no description of the penis of the husband, and this is very essential to the establishment of proof. Thus, there are some organs which, owing to their conformation, are more liable to be torn and to give issue to blood than others are. Thus, when the prepuce is long and tight, particularly when there is a fibroid ring at its end, also when the frænum is short, in these conditions very often fissures of greater or less extent occur, which may give issue to blood.

Then, again, cicatrices of chancres are frequently torn in the sexual act, and sometimes they are the seat of copious bleeding. In this man's case there was a cicatrix. These cicatrices sometimes, indeed very often, become eroded or denuded of their epithelium, and then they give rise to bleeding or oozing. In addition to this, let it be considered what a highly vascular and delicate membrane is that of the prepuce with its numerous folds. Besides chafes and fissures occurring when the prepuce is somewhat abnormal, how often do we find these same lesions of continuity in those which are not abnormal! Again, owing to obvious causes, newly-married couples are peculiarly liable to these little affections. Every practitioner who sees large numbers of cases of venereal disease will certainly say that lesions such as chafes and fissures which are capable of giving issue to blood are of very frequent occurrence. Indeed, the very frequency of occurrence has often called to my mind, in cases under inspection, the great risk women would have run had the patients been syphilitic. Now, between man and wife, such an occurrence will not usually lead to any thought or anxiety on the part of the husband, and he passes it over as trifling, whereas, if the same accident occurred in coitus with a person

at all liable to suspicion, he would certainly be very anxious as to the result. Now, it might be urged that we have no evidence upon which to suspect that blood was caused to flow in coitus between these parties. This is very true; but let it be considered how little attention would be paid to the fact if it occurred, and how readily and how often it would escape unnoticed, and how favorable all circumstances are to its being overlooked. Besides this, a fissure might have occurred, and yet have passed unnoticed, owing to the careless habits of the man. Now, we know, or it is fair to think so, from the statement of Dr. Smith, that he did not warn his patient, as indeed every practitioner is in duty bound both by moral and scientific reasons to do, that there was great danger, he being in the secondary period, of his communicating syphilis by the blood in the sexual act: consequently this man was ignorant of the peril involved. Not having been forewarned, such an occurrence as the slight tearing or abrasion of any part of the penis would not cause in his mind any alarm, and the fact, seeming unimportant at the time, would soon be forgotten, certainly would not be brought to the attention of the physician. On the contrary, even in a married man who has not been otherwise exposed, what are his feelings at experiencing the slightest uneasiness in the urethral canal, and at the sight of a discharge, even if it is so scant that it merely glues up the lips of the meatus? Certainly, in such a state, he would speak of his trouble quickly. Now, I think that these considerations render it highly probable that an abrasion or fissure might have occurred, and that from it or them blood escaped which caused the contagion. This probability is much stronger than that urethral mucous patches existed, as the former is in direct accordance with science, while the latter would be one of the very rarest of all exceptions.

Besides this, the circumstantial evidence offered by the case is, I think, more in favor of the escape of blood than of the occurrence of mucous lesions. Certainly the explanation by the blood-hypothesis does not require and has not received any straining at argument or perversion of known facts, whereas when we say that it was by semen we endeavor to controvert by one imperfectly-reported case a well-grounded belief or law, and a number of cases better known; while, if we accept Dr. Sturgis's theory, we must admit the existence of lesions which have never yet been seen, and which we are warranted by facts in thinking perhaps never will be seen. Besides this objection, it must be added that the evidence in the case does not offer the slightest pretext for thinking that there was any lesion of the urethral canal at the time of contagion and immediately after it.

It has often appeared to me very surprising that while the fact of the contagious nature of syphilitic blood is so generally known, or rather stated in books, the practical application of it as suggested in this argument seems to be very extensively overlooked, or rather not clearly appreciated. Thus, the text-books, while they state that the blood is contagious, do not bring out the bearing of the fact as fully as they should, and, owing perhaps to the want of illustrative cases, it is never submitted to careful examina-

tion and elaboration in clinical lectures. Therefore students go into practice virtually ignorant of this vitally essential point, while the practitioner, not having his attention drawn especially to it, fails to make practical use of it. Plainly stated, the case is this: that while physicians are aware of the contagious character of mucous patches, and upon occasions warn their patients of the fact, they in the great majority of cases fail to inform them of the similar nature of their blood, and of the danger of infection by it. Now, it is equally important that the latter fact should be explained as the former, and, indeed, I may say it is more important, for this reason, that the blood retains its contagious properties for long periods, indeed for indeterminate periods, consequently the liability to contagion extends for a similar time, while, although mucous patches are by their secretion so contagious, and are so apt to relapse frequently, yet they can be cured, and then they cease to be a source of danger. To apply this fact practically, supposing, as is most probably the case, that a man's blood is contagious during the whole secondary period, which in the average we state to be two years; now, during that whole time, if by chance that fluid is placed in proper conditions, contagion ensues; while, even if a patient has the most inveterate attacks of mucous patches, they certainly are present, and therefore contagious,—but let us say for one-half of that time, at the most. I have been struck by the want of attention paid, and, I may say, by the ignorance displayed, by very many, as to this contagious nature of the blood, and *I have seen numerous undoubted instances in which newly-married women have become syphilitic through this means, in consequence of the physician not having warned the syphilitic husband prior to marriage.* In several instances I have learned that they were informed of the probabilities of occurrence, and of the dangers of mucous patches, and assured that they were the only troubles to be feared. So strongly has this fact been impressed upon my mind that I in every instance, when it is necessary, warn patients very solemnly of the dangers of chafes and fissures about the penis. It is obvious that to the newly-married this warning is very necessary, and, indeed, I think it the duty of the physician to instruct men and women quite freely even of this fact. I am assured in my mind that, when the people generally understand this danger, much domestic unhappiness will be avoided, many innocent persons will escape syphilitic contagion, and there will be markedly fewer cases of infantile syphilis.

As regards the domestic relations, the occurrence of syphilis by this means is often the cause of suspicion and unhappiness. Thus, a man who, having been syphilitic, and being as he thinks cured, even knowing that mucous patches are contagious, by sad chance infects his wife. If at the time he has a fissure or chafe, it is healed and forgotten in a short time, if, indeed, thought of at the time; very soon his wife develops the initial lesion of syphilis, and he, not having, as he thinks, any syphilis about him,—as they say,—wonders how his wife became syphilitic, and it may be that very serious trouble

results. I will quote an illustrative case farther on. Suppose this man tells his story, and asks the advice of a physician who does not appreciate this point, what is the result? Indeed, I think I need not multiply examples; it is sufficient that this fact exists, and it is the solemn duty of the physician—who has so many problems to solve daily, involving oftentimes tender interests and the integrity of families—to know it thoroughly, and not only to know it, but to make practical use of it. So vitally important is this matter, that I think I shall not be accused of egotism if I detail my line of advice to syphilitics about to marry. Certainly, if it were arrogant on my part, if my counsel saved one person this serious disease, I think it would be acceptable. Now, then, when advising men, of course I insist as far as possible upon the lapse of at least two years from contagion, and even longer if the manifestations of syphilis show an unusually active state of the disease. At the end of this time, in seemingly auspicious cases, I inform them—if they have been treated regularly and for a sufficient time—that they are as well as they could be, perhaps even are cured, but that there are certain precautions to be observed and dangers to be avoided. I then carefully explain, or reiterate, as I have undoubtedly spoken of the matter before if they have been long under my care, the nature and danger of mucous patches and of ulcerative lesions generally; then I go minutely into the liabilities of contagion by the blood. I make this point very clear by warning them of the danger of chafes and fissures, and of the necessity of a temperate course. I then examine the penis, to see whether, owing to its conformation, it is liable to any lesion of continuity in coitus. If the frænum is short, and tends to curve the penis downwards in erection, and consequently is very liable to be torn by violent use, I recommend that it be properly treated by operation. If the prepuce is in such a condition that fissures or chafes are liable to be developed in it, I also suggest the danger and advise the remedy. When I have done this, I have done all that I can; and I have no doubt but that I have saved many persons from syphilitic contagion. These remarks may suggest to some the propriety of use, under these circumstances, of the appliances called *safes*; yet I think that they are so uncertain and so open to serious objection that their use should be discarded. Thus far I have alluded only to the fact of contagion from male to female; now, though the limits and scope of my paper do not admit of it, I must call attention to a point made by my friend Dr. Hyde, who suggests that menstrual blood of syphilitic women may possibly be the means of the transmission of the disease. I need not dwell upon the practical import of this suggestion. I think that I have now said enough to prove that this somewhat overlooked and unappreciated source of contagion is well worthy of the prominence which I have here attached to it.

At the risk even of being considered prolix, I think it is well to call attention to a case published in the *Philadelphia Medical Times* for February 7, 1874: it is contained in an article entitled "On the Communicability of Syphilis after it has been

Apparently Cured." The author, Dr. H. E. Woodbury, reports the case of a man forty years of age, who, in the spring of 1870, became syphilitic. Under treatment he was said to be cured, and, with the consent of the physician, was married in 1872, at which time he was apparently well. His freedom from syphilis was more apparent than real, for he was attacked by a syphilitic ulcer six months later.

Two months after his marriage, he called Dr. W.'s attention to a painful sore on his wife's genitals, and "very suspicious symptoms." No further history of the wife is given: it however may be judged from the context that the doctor regarded or suspected the case to be syphilitic. The woman declared that she was chaste, and the husband, asseverating his continence, under examination shortly afterwards was found to be free from lesions about the penis. The doubt in the attendant's mind was as to how the sore originated; and three consultants were unable to assist him to a rational conclusion. In his remarks upon the case, Dr. Woodbury says, "We can only add that in this case *some deception must have been practised or some mistake made*, as we verily believe." The italics are by Dr. W.

Now, then, here is a case in which in the newly-married wife of an undoubtedly syphilitic man an ulcer of the genitals is developed. The physician, failing to recall to mind the probability of the contagious nature of the husband's blood, and of the liability to infection of the wife in coitus, and not having the point suggested to him by the three gentlemen who saw the case in consultation with him, is in doubt as to the origin of the ulcer upon the genitals, and finally concludes that some deception was practised. In other words, the character of, as there is no reason for thinking otherwise, a pure and worthy woman is called into question under circumstances of which she is the innocent victim. I need not suggest how clearly and conclusively the doubt in this case could have been dissipated had this undoubted mode of contagion been borne in mind by the physician, and had the probable circumstances of the infection been suggested and explained to the husband and wife.

The bearing of this case is so forcible that I think it will do more to sustain my position than any argument, however forcible, would. When this source of infection comes to be generally recognized, we shall cease to read of these doubtful cases, and much misery of families will be averted.

125 EAST TWELFTH STREET, NEW YORK, Feb. 16, 1875.

DIPHTHERIA: A NEW TREATMENT.

BY H. V. SWERINGEN, M.D.,

Fort Wayne, Indiana.

I HAVE had some experience in the treatment of this disease during an epidemic which visited the city of Fort Wayne, Indiana, the present winter (1874-5); and, notwithstanding the fact that what success I had occurred in the latter period of the epidemic, which in all epidemics is usually considered the mildest portion, yet I cannot avoid attributing that success in a great measure to the change

I adopted in my treatment; and I believe that I am warranted in so doing by the facts that the disease was yet at this time quite generally fatal, and that out of a number of severe and well-marked cases I was so fortunate as not to lose a single one under my new treatment. I call it *my* treatment because I have never heard its theory suggested, nor have I seen it in print. I have not yet had an opportunity of testing its value in the *severest* or *most malignant* cases, such as occurred in the earlier part of the epidemic, but I feel confident that in a large proportion even of these, if adopted *early*, it will prove successful. The discovery which I have been flattering myself as having made—and it remains for future experience to establish its value—is, that *prompt cinchonism, followed by an alterative tonic, is, if not absolutely a specific, the most proper and successful treatment for diphtheria.*

It may be said, however, that quinine as a remedy in diphtheria is not new; that it is almost invariably given in the course of the disease. This is true; but it is equally true that it has never been given with any specific object in view, other than its tonic or antiperiodic effect. It has usually, in fact, in this disease, been given on the "hit or miss" principle. The remedies commonly considered of the most value in the treatment of diphtheria are the muriated tincture of iron, chlorate of potassium, carbolic acid, and nitrate of silver; the former three given both constitutionally and locally, the latter applied locally only. All the text-books which I have consulted seem to rely chiefly upon the above-named remedies.

It is the *condition* known as *cinchonism* which is produced by the administration of quinine in *positive* doses until its peculiar physiological effects are induced to a *marked degree*, that I contend is the *first grand object to be accomplished in the treatment of diphtheria.* This statement is based upon the confidence I have in the antiseptic properties of quinine *if properly administered*, and the belief that when the condition of cinchonism is fully established, the septic poison in the circulation is then neutralized; and this belief is founded on the *fact* that in every case that I have thus treated, just so soon as that condition was established, the exudation became detached without any local interference whatever; none during the whole course of treatment. Another important *fact* in this connection is, that the most severe and malignant cases I had were those in which it was most difficult to establish the condition of cinchonism. A little boy six years of age, son of C. L. Thomas, Esq., residing at No. 134 Jackson Street, Fort Wayne, Indiana, took sixty-four grains in forty-eight hours before he complained of "ringing in his ears or deafness;" but when this took place the membranes became detached of their own accord, his appetite in a measure returned, the swelling of the submaxillary glands began to subside, and in a comparatively short time he made a good recovery. In this case I did not make a single local application. In fact, I have abandoned local treatment altogether except in cases where it is absolutely necessary to remove excessive mechanical obstruction of the air-

passages, or where it is necessary to correct the fetor by disinfectants. I had six other cases under treatment about the same time, all of whom were well marked, and the line of treatment pursued in each was as follows:

R Quin. sulph., gr. xxxii;
Acid. tannic., gr. x;
Syr. simp., f3i;
Tr. ol. menth. pip., gtt. iii.—M.

Ft. mist.

Sig.—A teaspoonful every three hours until cinchonism is induced.

After which I administered the following:

R Potassii iodidi, gr. xxxii;
Potassii bromidi, 3ii;
Syr. simp.,
Tr. cinch. co., aa f3i.—M.

Ft. sol.

Sig.—A teaspoonful every three or four hours.

The above may be given alternately with the following:

R Tr. ferri chlor., f3ii;
Syr. simp., f3vi.—M.

Ft. mist.

Alum or ipecac as emetics are useful when the exudation shows a disposition to extend to the larynx, or when there is much difficulty of breathing from tumefaction of the fauces, or from accumulation of the pseudo-membranous deposits. Food,—milk, beef-tea, and stimulants,—brandy, wine, etc., constitute a very important part of the treatment.

If the principles involved in the foregoing considerations of the treatment of diphtheria be correct, may we not reasonably conclude that the same or similar treatment will prove of great value in cases of puerperal fever and erysipelas?

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF DR. T. G. MORTON.

Reported by J. J. KIRKBRIDE, M.D.

ENCIRCLING WOUND OF THE PENIS.

F. G., aged 44, was admitted October 30, 1874, with the following history. He had been drinking immoderately for some days; while in bed with his wife, had a difficulty with her regarding the possession of a few dollars. A fight ensued, which culminated in the wife seizing her husband's penis, which she pulled and twisted with all her strength, producing a severe wound, accompanied by serious hemorrhage. On admission, several days afterwards, a lacerated suppurating wound was found at the root of the penis, five inches from the glans, extending through the skin and involving the body of the organ, which it completely encircled, with the exception of a small isthmus on the under surface still remaining intact. The wound, which looked as if the circular sweep of a knife had been applied, gaped to the extent of half an inch, the skin being inverted around the edges, and the prepuce and penis very much swollen. At the clinic, October 31, Dr. Morton, after freshening the edges of the wound, approximated it by silk sutures. Frequent erections during the next

few days tore out most of these, however, and the parts are now healing by granulation.

Dr. Morton also described and exhibited the specimen from a case which occurred during his service in the hospital. A man, during an attack of mania a potu, had cut off his penis close to the body, with all the skin of the scrotum, and was, on admission, almost dead from profuse hemorrhage. The exposed testicles were finally covered by gradual cicatrization, and what remained of the penis was eventually glued even with the abdominal parietes, the urethra simply projecting on the surface, where its sensitive orifice was protected by a silver cap, held in position by straps around the body.

TWO CASES OF COMPOUND FRACTURE OF THE ELBOW-JOINT—EXCISION IN EACH CASE OF THE OLECRANON PROCESS.

M. J. M., aged 42, was admitted September, 1874. A few hours previous, had been kicked by a mule directly below the left olecranon process, which was entirely separated from the ulna; the joint being opened and the fore-arm luxated anteriorly. The olecranon was so much exposed and drawn upwards that Dr. Morton divided the triceps attachment and removed it, the wound being then carefully approximated with silver sutures, and the arm placed in a right-angled splint. Free suppuration was established during the next three weeks. Irregular chills followed the operation, and produced much prostration, but were controlled by large doses of quinine daily. The angle of the splint was constantly changed; the wound rapidly healed up, and, with the aid of a Stromeier's splint, good motion in the joint resulted.

A few hours after the previous case was operated upon, P. McJ., aged 51, was brought in with the same sort of injury, the result of a stroke from a drawing-knife, the first blow causing a scalp-wound with the chipping off of a thin layer of the skull, while the second blow produced an incised wound, completely dividing the left ulna close to the olecranon; the arm at the time being raised to ward off the attack. The olecranon was entirely separated and drawn upwards. As in the previous case, the attachment of the triceps was divided, and the olecranon process removed, the same treatment being adopted with excellent result, the wound closing up with fair motion in the joint.

TRANSLATIONS.

EXPERIMENTAL SEPTICÆMIA. — A communication from M. Feltz on this subject was read by M. Ch. Robin before the Académie des Sciences at a recent sitting. M. Feltz's researches are in continuation of those made some years ago by himself and Prof. Coze. They were undertaken with the view of ascertaining the infective power of septic blood compared with that of putrefied blood, and also of the septic activity of infinitesimal doses of both these kinds. The rabbit was taken, as before, for experimentation.

Four series of experiments were made by means of putrefied rabbit's blood. In the first, small quantities of the putrefied blood were injected, by means of a hypodermic syringe, under the skin of the animal's back. Seven rabbits were thus experimented upon, all of which died within a period of from three to six days, with the usual symptoms of infection. In the second series of cases, inoculation of the same blood by means of the lancet resulted fatally from infection in only one case out of nine. In the third series, inoculation of the same blood previously desiccated produced no effect what-

ever. In the fourth series of experiments, injection under the skin of a liquid which had been obtained from putrefied blood by means of dialysis gave no result in the case of the rabbits thus treated. The blood had remained for twelve hours in the dialyzer; the osmotic liquid manifestly contained bacteria similar to those of the blood, and, in addition, traces of albuminoid matters.

A fourth series of experiments comprised a number of injections with the putrefied blood, diluted to a greater or less degree. These resulted negatively, none of the animals experimented upon having succumbed with symptoms of infection.

The conclusion drawn from these experiments was that, in order to prove toxic, the putrefied blood must be introduced into the economy in a proportion at least equivalent to one degree of the Pravaz syringe. Inoculations with the lancet, with infinitesimal dilutions or with dialytic dilutions, do not bring about fatal results. A similar series of experiments undertaken with septic blood gave quite different results; the injections proving almost invariably fatal.

The result of these experiments shows that septic blood acts much more energetically than putrefied blood; that septicity augments with successive generations; that it remains the same, however small may be the quantity of blood inoculated, provided that the inoculation is made without any admixture. It is exceedingly probable that the failures to inoculate with infinitesimal or dialytic dilutions is owing to the fact that the septic substance does not mix well with, and is not dissolved by, distilled water.—*Gazette Médical de Paris*, December 26, 1874. X.

THE DIAGNOSIS OF CONSTITUTIONAL SYPHILIS (Kaposi: *Wiener Med. Presse*, No. 4, 1875).—It has been asserted by many that constitutional syphilis may occur in patients who have never had chancre; and this assertion has been made because individuals with this disease have been met with upon whom neither chancre nor trace thereof could be discovered. To express infection of this kind, where no local lesion is found which can be looked upon as the point at which the virus enters the system, the term "syphilis d'emblée" has been used. Hereditary syphilis, too, is also a species of syphilis d'emblée, for here there is no transmission of the disease by a chancre. It must not, however, be forgotten that the possibility of infection in this way is but a supposition, even if it is a well-founded one. It must be remembered that a patient may appear to have contracted syphilis without having had a chancre, because, at the time the examination is made, all traces of the local lesion have vanished. With regard to chancre itself, it is a curious fact that a large proportion of physicians recognize but the two typical forms of chancre, hard and soft, and find themselves in a certain degree embarrassed when they meet with a sore of venereal origin which does not exactly correspond with the features of these sores as set down in the books. This evidently arises from the fact that these two types of venereal sores are those most frequently met with, and also from the influence of the axiomatic phrases in which Ricord expressed his theories, which have become so closely incorporated into all the literature of the subject and have exerted so powerful an effect upon the minds of all observers. Ricord was perfectly justified in devoting so much attention to these two types, and the practitioner also is, for it is a question of much moment in the formation of a prognosis, since, as a rule, a hard chancre is the precursor of constitutional syphilis, while the soft sore is not followed by any general symptoms. Neither Ricord nor any one else has, however, asserted that only these two forms of chancre exist. On the contrary, writers upon this subject have always affirmed

that other varieties of chancre are to be met with, and, to express these varieties, numerous qualifying adjectives have been used.

If a closer examination of this subject is made, it will be found that a different form of expression must be used to characterize correctly the appearances which are met with. As a rule, there results, at the point at which the syphilitic virus is introduced, a certain tissue-change. This is sometimes of the type either of a hard or a soft chancre, but often, on the other hand, not like either; so that the possibility of this "local" or "primary" lesion presenting varied appearances must not be lost sight of. There is frequently seen at the point of inoculation a condition which cannot properly be called a chancre at all, if by this term any ulcerative process be intended. In the fossa navicularis in women there is sometimes seen a sharply-defined reddened patch on the mucous membrane, which is of the size of a small coin, which is scarcely if at all ulcerated, or which may even be smooth and shining; and still, if patients thus affected are kept under observation, it will be found that symptoms of constitutional syphilis follow lesions of this kind. Among women it is often difficult to discover the primary lesion of the folds of the mucous membrane of the genitals, and, in addition to this difficulty, the typical forms of chancre are relatively infrequently found. There are frequently seen, on the genitals of women, simple tubercles in the follicles, which cannot be distinguished from ordinary acne, but which later are metamorphosed into crater-shaped chancres of the follicles, or into papules, which are followed in due time by an outbreak of general syphilis. It is further established that the products of so-called secondary syphilis are inoculable, and are capable of producing constitutional disease.

This fact has been long known to clinical observers, but the investigations of Waller, Wallace, etc., first overthrew the doctrine of Ricord, that there could be no syphilis without a chancre.

From all this, it can be seen that it is a very difficult matter to assert in any case that constitutional syphilis has not been preceded by a local lesion, for it is highly probable, in such cases, that the excoriation through which the virus entered has healed before the examination was made, or that the lesion, although present, may elude detection. W. A.

THERAPEUTIC NOTES.

TREATMENT OF DIPHTHERIA AND SCARLET FEVER.—Dr. G. Mayer (*Jahrb. f. Kinderk.*, vii. 4) is strongly in favor of the treatment of diphtheria by ice. Even in children under one year he directs small pieces of ice to be put frequently into the mouth, followed, if possible, every minute or two by a teaspoonful of iced water. The ice must be pure, and therefore all artificially prepared is best. In severe cases the external use of cold, by means of an ice-bag applied round the throat, is very useful. The author has found that by this mode of treatment the fever soon diminishes, and the diphtheritic membrane is detached and expectorated. It is only in exceptional cases that the disease extends nevertheless to the larynx. But in one case the author was obliged, in order to reduce the temperature, to resort to cool baths. The latter he also found very useful in scarlet fever. Whenever the temperature exceeds 102° in scarlet fever the patient is to be placed for ten minutes in a bath of a temperature varying from 93° to 73°, according to the intensity of the fever. The effect of these baths in reducing the temperature lasts for two or three hours.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, FEBRUARY 27, 1875.

EDITORIAL.

THE AMERICAN MEDICAL ASSOCIATION.

NO. II.

WE have the authority of Holy Writ for the assertion that "It is more blessed to give than to receive," but, so far as our observation goes, there is only one commodity concerning which all men are agreed as to the truth of the saying. All our readers will, no doubt, grant to us this morning the more enviable position; but we cannot help believing that if our offering were accepted with thankful hearts it would be better for the American Medical Association,—*i.e.*, for the American medical profession.

The first gift that we have to offer is to the county medical societies: it is, Appoint as delegates the best known and most able men, irrespective of age, who will *promise to go*. To these delegates we say, Having made the promise, *go*. If there be an uprising of the profession all over the United States, the American Medical Association will at once assume national importance. If, however, that importance is to be maintained hereafter, in our opinion great care will always have to be exercised in selecting the places of meeting. If next year were not the anniversary of the nation's birth, we would say, by all means select Boston for the following session; as time is, however, of course Philadelphia will entertain the Association in 1876. We opine that the air of this latitude will be found even more salubrious than that of the great city of Denver, which, somehow or other, the Association has forgotten in its Western peregrinations.

There is one thing that sorely needs thinking about and discussion,—namely, what the Association can do, and what it cannot do; what should be its object, and what it should avoid.

In the first place, the *social* work to be accomplished by the Association is really of very great importance: to bring together prominent representative members of the profession from all parts of the continent so that they may fuse and unify is undoubtedly a great and most useful work. Upon this point, however, nothing more need be said; the matter is sufficiently plain. If the delegates go to Louisville, the social functions will, no doubt, be performed in a vigorous manner.

It is different with the question, What of scientific value can be achieved by such a body of men, and what are the best ways of reaching the maximum? There are two ways in which an association can advance the science or art of medicine: by discussions, and by encouraging individual work. A scientific debate, to be of real value, requires the highest talents and knowledge in those who take a part in it, and very little has ever been accomplished in this way in medicine save in the consideration of some great practical general question of a hygienic or purely clinical character. It is true that there have been in the world's history a few discussions of real value upon scientific medical subjects, such as the one upon tubercle in the London Pathological Society; but these debates were between men of the highest eminence and special training,—men who, no doubt, prepared themselves for the long-announced discussions in the most careful manner. Certainly nothing of the kind is possible at a meeting of the American Medical Association at present. It may be possible to have really valuable discussions of some purely clinical subject, but, if the past be any criterion, the *personnel* of the Association will have to increase in ability before this can take place; or, what is more probably the real necessity, some method of announcing the subjects beforehand must be found, for, with our present training, very few men in our profession, even of the highest talent and learning, would be willing to discuss before the world any of the deeper clinical questions of the day without special preparation. The Association may be able to wrangle over the crude assertions of a surgeon whose enthusiasm or contempt for the acuteness of his colleagues has led him to report half-cured cases as cures; but we do not believe that at present any really valuable clinical result is to be obtained by its discussions.

After all, the direct work done by associations

is in our science so small as to be comparatively nothing. Practically, all advances in the past have been made by the labors of individuals. The true work of societies at present is, therefore, to foster and encourage individual efforts. It is in this respect that we think our American Medical Association has failed most utterly; although it does disgrace itself continually by offering a beggarly hundred dollars for original essays, and yearly gets some which would be dear at any price.

In the name of American medical science, which is starving for want of encouragement, we beg of the Association to do something that shall be worthy of itself, and not endeavor to get what are among the highest results of human intellect—original researches in the most difficult of sciences—for a college prize. How infinite must be the conceptions of the leaders of the Association of the value of original researches! Perhaps if they themselves had performed more, they would have clearer ideas as to the amount of talent required, the expenses incurred, and the enormous labor involved in any first-class piece of original research. A hundred dollars! and the investigator expected to entomb his article in the Siberian wastes of the Society's Transactions!

Let the Association offer five hundred or a thousand dollars for an original essay or lecture to be delivered before it, and appoint judges who are not afraid to say no, and we may have some result of which we can be justly proud. "Hold! we have not the money to do this and publish our Transactions." Then stop publishing these Transactions, and put an end to our great yearly disgrace. In this day of competitive journalism, the medical press may be relied upon to publish whatever is of value,—a very small percentage, to be sure, of that which fills the massive tomes with which the Association has loaded our library shelves; but we are of the old-fashioned opinion that what is not worth publishing had better not be published. It is only the inveterate bibliophile who believes that what was worthless in manuscript becomes a treasure when clothed in printers' ink.

HOMŒOPATHY IN ASIA.—A new Chinese remedy for worms, syphilis, vomiting, and skin-diseases, and possibly for any other kindred malady for which the patient may take it, is prepared as follows: Maggots are taken from privies and washed, then dried in the sun, fried, pulverized, and either made into pills or eaten in powder. We think it would be better for the Chinamen not to get these diseases.—*New York Medical Record*.

LEADING ARTICLES.

THE USE OF COLD IN FEVER.

NO. III.

ALL those who have used the cold baths freely and successfully in typhoid and typhus fevers appear to be agreed that, although the mortality is very much reduced, the duration of the disease is only shortened in that complications are avoided. As, however, the patient is left by the disease much stronger than he is when the expectant method of treatment is pursued, convalescence is much more rapid than under the old plans.

The effects of the anti-pyretic treatment upon the symptoms of the disease are stated to be very marked, the intense prostration, delirium, stupor, carphologia, involuntary passages, and other manifestations of the typhoid state being avoided. It is affirmed that the relief afforded is so evident to both patient and attendants that they soon eagerly acquiesce in the regular employment of the cold baths, although to the one the sensations are usually very disagreeable, and for the other the labor and attention required are very much increased. A very practical question, but one which we are as yet scarcely in a position to answer fully, is, What are the contra-indications to the bath? According to our old ways of thinking, bronchitis and pneumonia would especially seem to be in the way of the use of cold in cases of fever. The serious lung-affections of these fevers are, however, largely dependent upon the general adynamia, and this adynamia is in turn largely the result of the excessive temperature. Accordingly, the German investigators have not found the baths to do harm in the pneumonias of these fevers. Liebermeister, who has had more experience than any other man, says that "pneumonia, hypostatic congestion, and the like offer no reason for suspending the baths; the hypostatic troubles sometimes disappear under their use." The same authority, however, somewhat inconsistently, it seems to me, affirms that perforation of or hemorrhage from the bowels is a contra-indication to the use of cold in fever, because cold has a tendency to produce determination of blood to the internal organs. The experience of Wunderlich (*Schmidt's Jahrbücher*, Bd. clvi. p. 101) is, however, very much opposed to this idea of Liebermeister's. He treated sixteen cases of severe intestinal hemorrhage with cold baths, with but two deaths; neither of which resulted directly from the hemorrhage, one being from intestinal perforation and one from severe pneumonia. This mortality is certainly a very small one, for out of thirty-two cases Griesinger had ten deaths; out of twenty-one Jenner lost seven; out of fourteen Gietl lost six; and Jaccoud had six deaths in six cases. (*Pathologie Interne*, t. ii. p. 758). Bäuer, however (*Schmidt's Jahrbücher*, Bd. clvi. p. 101), is in agreement with Liebermeister in believing that the baths should be discontinued during intestinal hemorrhage. Yet their views seem to be based upon preconceived theory rather than upon actual trial.

Thus, Liebermeister says, "I have thus far ordered the baths entirely discontinued as soon as even slight hemorrhage from the bowels occurred." Menstruation appears not to be looked upon as a contra-indication. On the whole, the testimony seems to me to show that no local internal disease ought in the present state of our knowledge to be looked upon as absolutely contra-indicating the use of cold baths when the temperature is high in typhus or typhoid fevers.

It is otherwise when there is a general tendency to collapse,—when the heart is so weak that local stases of blood occur in almost all the internal organs. Under these circumstances the circulation has not sufficient power thoroughly to equalize animal heat, so that it is said to be entirely possible to cool the exterior of the body several degrees without materially affecting the temperature of the interior. One of the severe accidents which it is affirmed has very rarely followed the use of the cold bath in pyrexia is a sudden collapse, and clinical experience seems to indicate very strongly that when collapse is already existent the cold baths should not be administered.

In no disease attended with a long-continued pyrexia has the cold-water treatment been employed upon so grand a scale as in typhus and typhoid fevers; but the results there obtained are sufficient to indicate its usefulness in allied diseases. Of all the exanthemata, none is more constantly attended with excessive temperature than is scarlet fever. In this disorder the testimony to the value of cold is very strong. Going back to Cuvier, who really first systematized the abstraction of heat in fever, we find that he habitually practised in the most heroic manner cold affusions in the treatment of scarlet fever, and claimed the greatest success for the measure. Since his day the remedy has been employed with asserted good results by various observers, among whom may be mentioned Gérard, Bruère, Gianini, Armstrong, Laycock, Rilliet and Barthé, Trousseau, and Hiram Corson, of this State. The evidence is, unfortunately, too much generalized to allow of its being put in a statistical form, but for an extended résumé of it the reader is referred to the excellent article in Meigs and Pepper's work on the diseases of children. In almost all of these cases the cold was applied in the form of affusions, a method which is certainly far more terrifying to the child, and probably less efficient, than the cold bath. Recently, Dr. G. Mayer (*Jahrbuch für Kinderkrankheiten*, vii. 4) has been placing the child in a bath of from 93° F. to 73° F. (according to the intensity of the fever) for ten minutes, whenever the temperature rises above 102° F. He affirms that the effect was most beneficial, and that the reduction of temperature usually lasted for several hours. In *diphtheria*, cold bathing has been used to some extent, with seemingly good results. In both this affection and in anginose scarlatina it is of the utmost importance to combine the cold bathing with the local application of the ice-bag or ice-poultice to the throat.

It is in the highest degree probable that systematic cold bathing will be found serviceable in all blood-

poisonings with high temperature, such as smallpox, erysipelas, pyæmia, etc., but as yet we have no clinical evidence of moment upon the matter. The high temperature that prevails in sthenic pneumonia and certain other inflammatory diseases would appear to indicate the abstraction of heat; but how far the local disease will be advantageously or disadvantageously affected in these cases is as yet an open question. The only record of the systematic employment of cold bathing in inflammation of the lungs that I have met with is by G. Mayer (*Schmidt's Jahrbücher*, Bd. cxlix. p. 347). He is stated to have found that defervescence was materially hastened both in men and in children. Niemeyer and other German authorities advise the liberal use of ice to the chest.

H. C. W.

CORRESPONDENCE.

NEW YORK, February 9, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

AT a meeting of the New York Medico-Legal Society, recently, Mr. Edward Paterson, of the New York bar, read an exceedingly interesting paper entitled "Monomania as affecting Testamentary Capacity." After a few preliminary remarks, he said the imperfect condition of the law is displayed not only with reference to insanity, but there is current in the decisions of the courts, and in the general literature of the law, much of serious error respecting mental disease as influencing the testamentary capacity of the person affected by it. What is the most noticeable is that the state of legal knowledge and the results of legal decision on this subject seem to fluctuate between opinions of a hundred years ago and those of recent times; the former re-appearing and being reasserted when least anticipated, and receiving application and enforcement in the most unexpected quarters; and more especially is this to be observed in those litigations the facts of which indicate that the person whose testamentary act is assailed upon the ground of incapacity to make a will was, or was supposed to be, the subject of that mental malady which is now known to be a distinct and peculiar condition, and to which is assigned the term "monomania." By some it is claimed that any delusion disqualifies a person from making a will; while others assert that the old dogmas as to absolute alienation of mind are the true rules of decision on questions of testamentary capacity.

The general inquiry in all investigations concerning the mental condition of a testator should be, Was, or was not, the individual *compos mentis* at the time of the performance of the testamentary act? This is substantially the test as adopted by the court of appeals of the State of New York. That court, in the Parish will case, held that, "in law, the only standard as to mental capacity in all who are not idiots or lunatics is found in the fact whether the testator was *compos mentis* or *non compos mentis*, as those terms are used in their fixed legal meaning."

A lunatic, or one who is the subject of general mental derangement, is absolutely *non compos mentis*, and cannot make a will, except during the supervention of a lucid interval.

As to the term "lucid interval," the question is mooted as to whether there is any other condition than that of the presence or absence of the mental disturbing cause. If mental maladies are attributable to structural changes in the brain, it seems strange that there should be a suspension or cessation of the processes or the effects of processes operating such a change, and which suspension or cessation is merely temporary and intermittent; but the doctrines of the law on this subject are deeply laid, and now seem to be of general acceptance in the courts.

That unsoundness of the mind which is involved in all judicial inquiries as to a testator's ability to make a valid will may be either of two descriptions,—viz., general insanity or partial insanity. The recognition by the law of these divisions, which shortly necessitated the adoption of a rule especially adapted to each, marks a great and important era in the judicial history of insanity. Prior to the days of the American Revolution, the distinction, if taken by writers, or advanced by the more progressive and better-informed of the medical profession, had no favor in the courts of law. The English courts formerly entertained jurisdiction to avoid instruments upon allegations of mental incapacity only in cases of "total loss of understanding:" when "one by grief, sickness, or other accident wholly loseth his understanding." In the criminal courts, some attempt had been made to establish the doctrine that limited insanity excused crime; but the effort was unsuccessful.

Each of the two chief divisions of mental incapacity has applicable to it its peculiar and distinct rule of law:

1. When the evidence shows the testator to have been totally insane shortly before the time of the execution of the will, testamentary incapacity is presumed to have existed at the time of its execution, and the *onus probandi* is thrown upon those claiming the validity of the instrument to countervail this presumption by evidence of a lucid interval during which the testamentary act was performed.

2. In the case of partial insanity, or partial unsoundness of mind, generally evinced in the form of monomania, it devolves upon the contestants to show that the will is the direct offspring of that insanity; or, in other words, the burden of proof is upon the contestants to show that the partial insanity existed at the time of the execution of the will, and that to its existence and to its operation in and influence upon the mind of the testator their disherison is to be attributed.

Several instances cited prove that in cases of partial insanity or monomania, unless the contestants can clearly trace their disherison to the delusion of the testator existing at the time of making the will, the legal presumption is of testamentary capacity, as this always attaches until it is countervailed by some express proof.

The rule with relation to disqualification from testa-

tory power in cases of monomania as stated finds valuable illustration in cases in which delusions of a more or less insane character have been proven as isolated conditions, not directly affecting the wills or depositary provisions of those subject to them (and in which cases, therefore, the testamentary acts have been sustained), as it does in those in which from their circumstances the inference was inevitable that the existence or operation of the delusions caused the testator to withhold his bounty from those who should have received its benefits. The essayist summarized his views, by way of conclusion, as follows:

The law as it now stands and should be administered upon the subject of partial insanity (and almost all the cases of partial insanity are cases of monomania purely) is of comparatively recent origin; that it is the product of improved knowledge respecting the diseases of the mind, and of more liberal as well as accurate views respecting the freedom of the will, and the restraints proper to be put upon testamentary powers; that it consists of a rule applicable to all cases of the character under consideration, but one which is affected by the general tendency of the courts to revert to antiquated ideas upon topics resting purely in authority,—a rule which is liable to be lost sight of in the attempts to find in cases of monomania evidence of a general insanity. It does not require that to prevent the making of a valid will a man must be bias and thwart in all his mental processes; but it is a rule which discriminates in favor of those who are the natural objects of his bounty and affection; and it prevents injury and injustice being done to such because of a testator's delusion, fancies, and irrational prejudices, in cases where they have evidently affected his acts; but it does not deny the testamentary privilege to the man whose eccentricities, beliefs, follies, or infatuations may be as absurd and fantastic as the incoherencies of a half-remembered dream, provided in all other affairs of life he is of competent judgment, and his vagaries have not led him to do injustice to his kindred, or to harden his heart against those who are the proper objects of his testamentary bounty.

REVIEWS AND BOOK NOTICES.

ELECTRICITY FOR NERVOUS DISEASES. Translated from the German of Dr. F. FIEBER, by GEORGE M. SELWIG, M.D. 8vo, pp. 60. New York, G. P. Putnam's Sons, 1874.

MEDICAL AND SURGICAL USES OF ELECTRICITY. By GEORGE M. BEARD, A.M., M.D., and A. D. ROCKWELL, A.M., M.D. Third Edition. 8vo, pp. 800. New York, William Wood & Co., 1875.

Putting these volumes side by side reminds one of the enormous elephant and the mastiff which are such close companions in our Zoological Garden. Yet the two books have at least this in common, that they approach their subject from the one point of view. For, like theology, electro-therapeutics has two distinct methods, that of faith and that of doubt, and it strikes us that what some of the old theologians taught, "to doubt is

to be damned," must be the creed of many of the prominent modern electro-therapeutists. Unfortunately, we are, like Thomas of old, a doubting disciple, and, whilst we do not presume to take the Hebraic style of argument,—Show me the other man who has seen one hundred thousand cases of skin-diseases, and I will listen to what he has to say contrary to my teachings,—yet, the farther we have progressed in practical experience with electricity, the greater reason have we seen for not putting confidence in princes. The works before us are, then, works of faith as well as of healing. The smaller of them we shall dismiss with a single quotation: "In *migraine*, electricity is a true specific." In our experience, migraine is the one form of so-called functional neuralgia in which galvanism is of the least possible use.

The work of Drs. Beard and Rockwell is an exceedingly elaborate and complete one, and may be accepted as one of the best existent expressions in regard to electro-therapeutics from the enthusiastic point of view. As an instance of how faith affects a man's reasoning power, we cite the following, which is brought forward as proof of the anæsthetizing value of the electrical current: "We had teeth extracted while a strong faradaic current was passing through, and feel assured from this personal experience that electricity caused the pain to be less sensitively felt. That the pain caused by the prick of a pin, for example, is less sensitively felt when a strong faradaic current is passing through the part where the puncture is made, we have practically demonstrated on the hand and other parts of the body." Probably a red-hot iron would also have an anæsthetizing influence, so that a prick of a pin during its application would not seriously incommode the patient. Again, speaking of perspiration being produced by galvanization of the cervical sympathetic, "To produce sensible perspiration usually requires a strong current and a long application. We have observed this effect more frequently and more markedly in the susceptible and the nervous." When a boy, the mere quiet statement, "After supper I will have a settlement with you," produced a very sensible perspiration, which in our ignorance we have attributed to the sympathetic ganglia at the other end of the trunkal ellipse! Leaving all facetiousness aside, of course pain and excitement will make a strong man sweat, much more a nervous person, and of course the same influence will alter the heart-beat. The whole argument which Drs. Beard and Rockwell bring forward to prove galvanization of the cervical sympathetic during life appears to us a fair example of the way in which strong faith and a want of application of the doubting principle have raised a mighty superstructure of electrical therapeutics. Our authors acknowledge (p. 129) "that the ordinary therapeutical measures for electrizing the sympathetic do not produce the same effects as direct applications to the ganglia." Yet they claim that in these measures we do galvanize the same ganglia; and why? Because in their experiments, using very strong currents, they have seen hysterical women become hypnotic, a sense of warmth diffused through the system, with sensible perspiration, the pulse sometimes accelerated, sometimes lowered, and because other observers have seen or imagined they saw the pupil sometimes slightly dilated, sometimes slightly contracted, and the retinal vessels sometimes dilated, sometimes contracted; all of which inconsistent and contradictory phenomena, to our mind, evidently were the result of psychical influences exerted upon either the observer or the patient. Galvanization of the sympathetic ganglia when performed by the physiologist yields *always* a fixed, definite result so plain and so visible that a child could not mistake it; the laws which govern the passage of the electrical currents and the anatomical structure of the neck are

such as to render it exceedingly improbable that any appreciable amount of electricity can reach the ganglia when the current is applied to the exterior in the usual method, and the clinical evidence of any action seems to us like bones taken from an ancient cemetery,—fair to look at, but falling into powder when touched. We have experimented largely upon the living animal and upon man, and do not believe that it is possible, by the use of any ordinary therapeutic currents, sensibly to affect the cervical sympathetic. Yet electro-therapeutists, if we are to believe their statements, cure the most distant diseases by galvanization of the cervical sympathetics; diseases, too, which have no anatomical or physiological relation with the ganglia. Verily, the spirit of Hahnemann must be again among us.

One thing that has aided in increasing the asserted value of electro-therapeutics is the absolute forgetfulness so often indulged in of the principles of electrical science. Our authors are not altogether clear in this matter. It follows as an absolute necessity from Ohm's law that a galvanic current has but one attribute,—current strength; our authors fully endorse not only Ohm's law, but also this generalization, in that they say "large cells do not send more quantity electricity through the body than small cells of similar character;" yet we read (p. 142), "so obtain a number of currents varying in quantity, tension, and physiological power."

In concluding this review, we wish to state clearly that we do not mean to criticise the book of Drs. Beard and Rockwell so much as the school to which it belongs. We recognize its authors as able, laborious men, although we do not believe in the correctness of their methods of generalizing, and of their deductions. Yet in these things they are certainly in accord with the vast majority of the writers on electro-therapeutics, and we are almost alone. It is with great heartiness that we recommend our readers who want a book viewing the subject from the stand-point of enthusiasm to buy the work of Drs. Beard and Rockwell, not merely because it is American, but because it is one of the most complete in the language. We beg of them, however, to remember that there is a spirit of enthusiastic faith which in science means death, and to season their trial of the teachings of the book with that spirit of doubt which is at the basis of all true progress in medicine.

H. C. W.

SELECTIONS.

HEMORRHAGIC INFILTRATION OF THE PANCREAS AS A CAUSE OF SUDDEN DEATH.—Certain observations recently made on this subject by Professor Zenker, of Erlangen, and communicated by him to the meeting of the German Scientific and Medical Association at Breslau, would appear to be of great importance to the physiologist, practitioner, and medical jurist. Cases of hemorrhage into the pancreas, associated with sudden death, have very rarely been recorded; they are probably more common than is believed, for Zenker met with no less than three within twelve months (*Daily Bulletin of the Forty-seventh Meeting of the German Scientific and Medical Association*). The facts observed were very nearly similar in each instance: a corpulent subject died suddenly, or was found dead; post mortem, the only fresh pathological appearance was extensive hemorrhagic infiltration of the pancreas and neighboring connective tissue, and advanced fatty degeneration of the pancreatic parenchyma. Further, there was found, in two of the cases, bloody effusion in the duodenum; and, in two, excessive hyperæmia of the semilunar ganglion.

The coincidence of these remarkable pathological conditions with the occurrence of sudden death indi-

cates, according to Zenker, the great importance of the observation from a forensic point of view: henceforth the pancreas must not be omitted in the examination of the organs after sudden death. In one of the cases, indeed, Zenker was able very strongly to urge that the subject—whose body was found in the water—had probably not committed suicide, but had dropped dead into the stream. On the other hand, these cases very readily remind the physiologist and surgeon of death by mechanical injury to the abdominal viscera,—of what is usually termed “shock.” It is an interesting fact that in two of the cases, as has been described, the semilunar ganglion was hyperæmic; and it is further a fact that in one at least of these the heart was found in precisely the same condition as that of the frog after Goltz’s familiar *Klopfversuch*, or tapping experiment,—namely, relaxed, and empty. And Zenker believes that, whether directly or indirectly caused, paralysis of the heart must be regarded as the immediate cause of death in these cases.—*Medical Times and Gazette*, January 9, 1875.

TRANSPLANTATION OF THE CONJUNCTIVA OF THE RABBIT FOR THE CURE OF SYMBLEPHARON.—In December, 1872, Dr. Wolfe, of Glasgow, brought before the Medico-Chirurgical Society of that city an important paper on the possibility of transplanting the conjunctiva of the rabbit, and of introducing into the human tissues grafts from the lower animals, in cases of that most distressing and unsightly disease, symblepharon. As is well known, treatment of this very intractable condition has rarely been successful, and any means for remedying it are most welcome. Abroad, Dr. Wolfe’s method has attracted great attention, and the latest contribution to its history has been two cases related by Carl Becker, of Heidelberg, one of the most distinguished ophthalmologists on the Continent, in the *Wiener Wochenschrift*. It is, moreover, to be noted that other methods had been adopted in these, and had proved unsuccessful. In one of Professor Becker’s cases, too, he had a particularly bad subject,—a tiresome, troublesome child. No wonder, then, that in this case a portion of the graft died; but enough remained to effect a cure. The success which has attended these trials by Dr. Wolfe and Professor Becker not only proves satisfactorily that animal tissues can be incorporated with human structures, but also opens out many suggestions for the future. It may not be always necessary to employ the tissues of animals to obtain our end, but success by such means gives, as Herr Becker says, happy auguries for the future.—*Medical Times and Gazette*, January 23, 1875.

PENETRATING WOUNDS OF THE KNEE.—M. Gayet, Surgeon of the Hôtel-Dieu at Lyons, on the strength of eight cases treated in that hospital, arrives (*Lyon Médical*) at the following conclusions:—1. A penetrating wound of the knee-joint, made by a pointed instrument, and unattended by complications, is without danger, provided it be allowed to cicatrize in a state of rest and immobility. 2. The same wound may give rise to the most dangerous arthritis when not properly attended to. 3. The danger of arthritis is in direct proportion to the extent of the wound and the difficulties which impede its union by the first intention. 4. The complications dependent upon injuries of the bones are extremely serious; but fractures of the patella, however complicated they may be, need not, if they exist alone, lead to amputation or excision. 5. The presence of foreign bodies, however small these may be, induces arthritis and its possible consequences, and demands amputation or excision. 6. All things being alike, posterior wounds seem more serious than anterior ones, by reason of the density and the number of the tissues concerned, the presence of vessels, etc. 7. These conclusions having been deduced from observations made

in a hospital,—i.e., in a medium little favorable to conservative surgery,—they may be regarded as more favorable when applied to media of a more healthy character.—*Medical Times and Gazette*, January 30, 1875.

GLEANINGS FROM OUR EXCHANGES.

SYPHILIS (*Medical Press and Circular*, January 20, 1875).—Dr. Schuster, of Aix, comes to the following conclusions (*Deutsche Zeitschr. f. Prakt. Heilk.*, 1874):

1. No general mercurial treatment is required for ulcers appearing after suspicious contact. Local treatment suffices: cleanliness, and the external use of iodoform in powder or ointment. The reason of this axiom is, we cannot speak clearly about syphilitic infection until its manifestations appear, or generally before from three to five weeks after the suspected connection; during the three to five weeks’ period of incubation we are not in the position to recognize the entry of the syphilitic infection, and therefore there can be no need of speaking of mercurial treatment.

2. Against the primary induration, with swelling of the glands, we should adopt treatment by vapor-baths and iodide of potassium, since through these appearances it is made clear that the virulent infection has passed through the neighboring glands and entered the blood, and iodide of potassium is preferable in this stage to mercurial treatment, since experience teaches that when mercury is used too early it loses its effect when the disease remains a long time, and it requires frequently to be repeated.

3. Against the secondary and tertiary appearances of syphilis (exanthems, gummata, diseases of the bones and internal organs) mercury has its best indications. It is contra-indicated in those amyloid degenerations of the greater or lesser glands (liver, kidney, etc.), united with universal cachexia, which are often joined to the tertiary period; in such cases even small doses cause loss of strength and salivation. On the other hand, some disturbances of the health, unconnected with syphilis, do not exclude mercury. In acute epidemic diseases occurring with syphilis, we must shun mercury; these diseases already by themselves weaken the syphilis. Tuberculosis in syphilis is made worse by mercury. If, after a certain time, the syphilitic symptoms do not give way, although mercurial appearances show themselves, mercury must be left off; and here sulphur hot baths are useful in bettering the constitution and the symptoms of the disease, since they free the body from the mercury which has been used to saturation, and help to regulate the physiological processes.

CASE OF VARICOSE VEINS TREATED BY A NEW OPERATION (*The Lancet*, January 23, 1875).—Mr. John Marshall reports the case of a laborer, æt. 38, who suffered such severe pain from a varicose condition of the saphenous veins, particularly that of the left leg, that he was unable to work. Mr. Marshall operated for his relief in the following manner. After standing for half an hour with a carbolized cloth round the left leg, the patient was put under chloroform, and the operator then marked on the skin with ink the course of the tortuous vein below the left knee for about nine inches. At each end of this mark he ligated the vein by means of a pin passed under the vein, with a piece of bougie and a figure-of-8 suture over the vein; two other similar ligatures were placed above the upper one at distances of two inches apart, and a fifth ligature was placed two inches below the lower one. The pins, bougie, and threads had all been previously carbolized. Esmarch’s elastic bandage was then applied to the whole limb,

with the effect of completely emptying the varicose vein, even in the intervals between the several pins. He then made a straight incision through the skin from the top to the bottom of the tortuous ink-mark, and, with a director and knife, slit up the vein along the whole of the exposed portion. As the vein then formed a very large, irregular, folded mass at the bottom of the wound, he passed a ligature round it above and below, and removed it entirely with forceps and scissors, cutting through two large veins opening into it. A strip of carbolized gauze was then placed in the wound, and the limb put up in the complete antiseptic dressing. The operation was done under the carbolized spray. There was no bleeding whatever during the operation.

Two months later, the patient was discharged, cured, the diseased vein having been satisfactorily obliterated above and below the part which was removed. Mr. Marshall says that in future he should make an incision through the skin in a direction best suited to the position and form of the straight or tortuous vein, expose the vessel, which is very easy of accomplishment, put a carbolized ligature on it above and below, and then seize one end of it with a tenaculum forceps and dissect it out. The application of Esmarch's bandage would render this operation perfectly bloodless, and no subsequent hemorrhage need be feared from the lateral veins, however large, which open into the part removed, for this could be prevented by a long pad of gauze placed in the wound.

CASE OF AGGRAVATED SYMPTOMS OF RENAL CALCULUS CURED BY AN EXPLORATORY INCISION (*The British Medical Journal*, December 19, 1874).—Mr. Thomas Annandale reports the case of a woman æt. 36, who, about two years before she came under observation, had been seized with a pain in the left lumbar region, and, at the same time, passed blood with her urine. These symptoms had continued more or less since, but had become much aggravated during the last five months. The patient was somewhat emaciated, and she complained of pain over the region of the left kidney, shooting down in the direction of the ureter. There was frequent micturition, with pain in the act; and an examination of the urine showed the presence of blood, pus, and crystals of the triple phosphate in it. Her temperature was 100.4°. There was well-marked tenderness on pressure over the left kidney, but no fluctuation or enlargement could be detected. The patient's other internal organs were apparently healthy, but she suffered from attacks of vomiting. Internal sedatives, hypodermic injections, and soothing external applications were carefully tried, but without affording any relief. As the symptoms pointed very markedly to an irritation of the left kidney, caused, most probably, by the presence of a calculus, an exploration was recommended, and was consented to. An incision, about seven inches in length, was accordingly made in the left lumbar region, and was carried along the outer border of the erector spinæ muscle, and, the layers of the lumbar fascia having been divided and the fascia transversalis scratched through, the kidney and upper portion of the ureter were freely exposed. A most searching examination of the kidney and greater part of the ureter was made, but no abnormal condition of the organ could be discovered, and no calculus could be felt. The operation was performed under the antiseptic spray, and, the edges of the wound having been brought together with antiseptic silk stitches and a drainage-tube inserted, carbolized muslin was applied in the usual way. For the first three days after the operation the patient suffered severely from sickness, but this was relieved by small quantities of opium, and iced champagne and brandy. In a few days she was entirely free from the old pain and other symptoms,

which had not returned during a period of six months. The wound healed easily, and the cure was apparently complete.

TUMORS (*The British Medical Journal*, December 19, 1874).—In some observations on the structure of tumors in relation to their character and clinical history, Mr. W. S. Savory advances the following theories:

The difference between homologous and heterologous growths is this: that in homologous growths the development is normal, but is carried out in the wrong place and under abnormal conditions; in heterologous growths there is more or less wide deviation from normal development. But there is no defined line of demarcation between the two. The whole difference turns upon the direction development takes, and the degree to which it proceeds. The tissues which are simplest in structure and mode of development are most apt to form the substance of tumors, as, for example, connective tissue. The most elaborate tissue in these respects—striated muscle—is very rarely, if ever, found as a distinct morbid growth, and it is comparatively rare to find even unstriated muscle as a separate mass in the substance of tumors. In the elementary structures of tumors, there is an inverse ratio between the tendency to progressive metamorphosis and the tendency to reproduction. The less the structures of which a tumor is composed tend to change from their primary or embryonic form, the more abundantly will they multiply; so that those tumors whose structures retain most nearly their primary form are the most malignant. And as the structures of a tumor are capable of transformation, so do they lose their power of repetition; so that those tumors which consist most completely of fully-formed tissue are the most innocent.

VENESECTON IN THREATENED ŒDEMA OF THE LUNG.—Dr. E. H. Hamill, of Islip, N.Y., contributes the following item of experience:

Mrs. L., aged 46 years, height 4½ feet, weight 150 lbs., on January 5 started to walk three-fourths of a mile to catch a train to New York. She felt perfectly well at starting, with the exception of a slight cold she had contracted two days before. After walking a few rods she felt some difficulty in breathing; although she walked slowly, the dyspnoea increased, she was obliged to stop, and in a few minutes became unconscious.

When seen by myself, her condition was as follows: unconscious; lips, face, and hands blue; pupils dilated; urgent dyspnoea, with constant effort to cough; a thin serous sputa running from the mouth; tracheal râles abundant, and easily heard at the bedside; pulse scarcely perceptible, slow; auscultation revealed abundant moist râles all over the chest. Diagnosis: congestion, with rapid œdema of the lungs; prognosis: death imminent.

Treatment.—Ten ounces of dark, almost black, blood were taken from the arm. The effect was surprising; the tracheal râles disappeared, and the breathing became easier. Administered three gtt. croton oil. In one hour the patient was conscious, all alarming symptoms were gone, and the next morning she was pronounced well.—*Medical Record*.

BELLADONNA IN THE TREATMENT OF PROFUSE PERSPIRATION (*The British Medical Journal*, December 19, 1874).—Mr. Anthony Butler has prescribed belladonna to upwards of thirty patients, most of them suffering from phthisis pulmonalis, but a few from other diseases. It was given at bedtime in pill, in doses of one-eightieth of a grain. The results have been very encouraging. In about one-half of the whole number of patients, after from one to four pills the perspiration was either checked altogether or diminished in amount.

In other cases no decided effect was produced till it had been used for about a week or ten days. In about a third of the cases no apparent benefit resulted, and the medicine was discontinued. In some of these cases the perspiration did not recur in a few instances, even after the medicine was stopped; but in others it returned, and was again checked when the pills were resumed.

INCONTINENCE OF URINE IN CHILDREN (*The Boston Medical and Surgical Journal*, February, 1875).—Dr. D. H. Hayden, M.D., believes that the four points which seem to hold out the best prospect of curing this complaint are—

1. The training the child to retain its water, in the daytime, as long as possible.
2. The use of the cold douche.
3. The moderate use of fluids towards night, and total abstinence from tea.
4. The internal use of belladonna, given in increasing doses till its specific effects are produced.

MISCELLANY.

A MEDICO-LEGAL ARGUMENT AGAINST CREMATION.

—It is stated in the *Allahabad Pioneer* of November 23 last that the results of the inquiry into the attempt at poisoning Colonel Phayre, the Political Resident at Baroda, have been communicated to the Government of Bombay. It is said that the man who gave the poison to the Resident's servant or servants died suddenly in the city on Tuesday last, and that his body was burned almost immediately afterwards. It is suspected that the man has been poisoned. However great may be the sanitary advantages of cremation over burial, there can be no doubt that the former system of disposal of the dead opens a ready way for getting rid of the traces of poison; and until the obvious objection to cremation for this reason be removed by stringent precautionary measures, it is hardly likely or desirable that it should be generally adopted.—*Medical Times and Gazette*.

A GOOD deal of laughter was occasioned in the French Chamber the other day, when Dr. Testelin, in demanding a school of medicine for Lille, in addition to those proposed for Lyons, etc., declared that the number of doctors had decreased in the town that he represents, while the population had increased. The doctor appeared astonished at the amusement caused by this statement.—*Medical Record*.

WOMEN-DOCTORS IN RUSSIA.—Fourteen women have this month completed their medical studies at St. Petersburg, and are fully qualified to practise. The Society for Aiding Sick and Wounded Soldiers has energetically supported the women-doctor movement in Russia.—*Medical Times and Gazette*.

AN AFFECTING DISSECTING-ROOM SCENE.—The janitor of an Indianapolis medical college was deeply affected on recognizing his mother-in-law on the dissecting-table. His grief was the more poignant from the fact that he had himself carried the stolen corpse up three flights of stairs.—*Medical Record*.

READY FOR AN EMERGENCY.—According to the editor of the *Union Medicale*, a female practitioner in Paris was recently so overcome by the gush of blood in a case of post-partum hemorrhage that she fainted. By the time she recovered, the patient was dead.

NOTES AND QUERIES.

"CRITICISM" CORRECTED.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

In your edition of February 6, 1875 (no thanks to the writer, however), appears what is "so called" a "criticism" upon an "hypothesis" assumed to have been claimed by myself in article iv. vol. xx. No. 5, Whole No. 116, of the *New York Medical Journal* for November, 1874.

I do not intend to reply to the "critic" professionally (at least not at this time), for reasons which follow:

1. He does not quote my article "candidly and honestly," or "in full;" and
2. What is quoted is done (to be generous) in a slovenly manner; and
3. The text seems to have been "criticised" without due regard to its subject-matter, either in letter or import.

Far be it from me to unjustly impeach the motives of any one, but when twenty-three and a fraction of lines which contain qualifying phrases are omitted by our "critic" from my article, then and there is the accepted time to cry for further light.

For the information of the profession, I will state that I still retain the views embodied in the criticised article. I hope at some future time to amend that article. By the assistance of time, which is the great developer of all that is valuable in science, literature, and arts, as well as men, I shall also enumerate other syphilitic lesions which were evolved during the treatment of the case, and which were inadvertently omitted in my article.

With respect,

ISAAC SMITH, Jr., M.D.

FALL RIVER, MASS., Feb. 11, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—In the *Times* for January 9, among the clinical notes contributed by Dr. William Hunt, I notice the heading, "Are the Kidneys Active Eliminators of Ether?" In this connection, a case which I had the opportunity of observing about a year ago may have some interest.

The patient, a gentleman of about fifty, was to be subjected to an operation upon the eye, for which it was necessary to administer ether. As he was very readily nauseated, and as, of course, vomiting was to be avoided if possible, the ether was carefully given, but, nevertheless, a very considerable quantity was inhaled before unconsciousness was produced. After the operation I fully expected nausea, but of this there was not a trace. The patient, however, urinated freely, passing at frequent intervals a large amount of urine, which evolved an enormous amount of ether vapor.

I mentioned the case at the time to several of my surgical friends, with the suggestion that perhaps the administration of a diuretic before the inhalation of the ether might obviate some of its unpleasant after-effects, but, so far as I am aware, the experiment was never tried.

Very truly yours,

H. B. HARE.

THE writer of the letter published in our issue of February 6, concerning the use of an infant's ring in lacerated wounds of the scalp, was Dr. James M. Laing,—not Janes, as we interpreted his chirography.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM FEBRUARY 16, 1875, TO FEBRUARY 22, 1875, INCLUSIVE.

KNICKERBOCKER, B., ASSISTANT-SURGEON.—Granted leave of absence for one month on surgeon's certificate of disability, with permission to leave the limits of the Department. S. O. 10, Department of California, January 30, 1875.

BENTLEY, EDWIN, ASSISTANT-SURGEON.—Granted leave of absence for one year. S. O. 28, A. G. O., February 16, 1875.

SATURDAY, MARCH 6, 1875.

ORIGINAL COMMUNICATIONS.

ON THE USE OF NITRITE OF AMYL IN VARIOUS FORMS OF SPASM, AND ON ITS VALUE AS AN AID TO DIAGNOSIS.

Read before the Philadelphia College of Physicians, February 3, 1875,

BY S. WEIR MITCHELL, M.D.,

Member of the National Academy of Sciences.

THE history of the employment of nitrite of amyl in epilepsy and in other forms of spasm is brief, and necessitates the mention of but few persons. Excepting its use in angina pectoris and in asthma, this powerful agent had been little resorted to when, in April, 1872 (see *Philada. Med. Times*), I reported cases of its use to arrest epileptic attacks. During the same year I advised Dr. Jenks to test its value in puerperal eclampsia, which he accordingly did do, reporting his success in the same journal in 1873. During that year (*Arch. Sci. and Prac. Med.*, No. 4, p. 311, C. E. Brown-Séquard and E. E. Séguin, New York), Dr. Wharton Sinkler, then my assistant at the Infirmary for Diseases of the Nervous System, related a remarkable case in which nitrite of amyl had been freely used with admirable results. Since then, in the *Medical Times* and in the *Reporter*, July 25, 1874, I have more briefly alluded to the value of this agent as a means of diagnosis.

I make this statement as an introduction to what I shall have to say of the nitrite, for two reasons: first, because it shows that what I shall state is founded on no brief or recent experience; and second, because it seems to be unknown in England that it had been long used as an antispasmodic agent in America. I infer this from the fact that Dr. Crichton Browne (*West Riding Lunatic Asylum Medical Reports*, 1873), in a very able essay on nitrite of amyl in epilepsy, while recognizing its value, does not allude to its previous successful employment in this country.

In this present paper I propose to bring together all that I have done or suggested as regards the use of this powerful agent.

For more than a year I had been aware that nitrite of amyl would be a proper means to use in epilepsy. It was clear to me that the nitrite caused, with rapidity, fulness of the vessels of the whole head, and that near to the outset of an attack of epilepsy there is a condition of vasal spasm. I hoped that I would be able by the use of the nitrite to counteract this state of vascular contraction, and so to break the chain of morbid phenomena, and thus end the attack before its more disastrous consequences should follow. This reasonable expectation was not disappointed. I was, of course, well aware that in most cases of epilepsy there would be no time to secure the inhalation of enough of nitrite of amyl to produce an effect, but I was also aware that in at least two classes of epileptics the opportunity for its use would be given. There are rare examples of

epilepsy in which the warning of the coming on of an attack so far precedes the spasm and loss of consciousness as to enable the patient to inhale the nitrite. In other cases the patient has a succession of fits within a limited space of time, and being then, of necessity, in bed, is so placed that a watchful nurse may find time to use the nitrite. I waited long for my first chance, but in March, 1872, the opportunity came. I give this case at length as I first reported it in the *Philadelphia Medical Times*, April, 1872.

J. C., æt. 23, was excessively prone to self-abuse until, at the age of eighteen, he began to indulge to an extravagant extent in venery. At twenty he had a chancre, but thus far no secondary results. On the 4th of March, 1871, he became slightly intoxicated, went to a neighboring city, and for some days gave himself up to sexual excitements to such an extent, as he described it to me, as to show that either he had unusual virile power or that he exaggerated his prowess. Be this as it may, there is no doubt that he ran into great excess, and that the punishment was distinctly born of the offence. On March 9 he felt feeble but nevertheless had connection four times that night. On the 10th he had, twice, twitching of the left forefinger. On the 11th this grew worse, and on the 12th, after unusual sexual excesses, he had a prolonged spasm of the left arm. It began in the hand, and in a few minutes involved all the fingers in forced flexion. Then the wrist bent, and the flexed fore-arm was forcibly contracted. The attack, which surprised the patient but did not alarm him, ended with slight vertigo. A week went by without further trouble, when a series of complete epileptic fits began, always preceded by the local convulsions which I have described. The fits, which at first came on daily, soon lessened in number, and of late have recurred but once a week. On two occasions they have been sudden and without warning, but in all other cases the hand has been affected with spasm, followed in a few minutes by vertigo, twisting of the head to the left side, left unilateral convulsion, and, finally, bilateral spasms, with occasional tongue- or cheek-biting. The attack is followed by prolonged stupor.

Many remedies have been vainly employed, and even the bromides in full doses failed to do more than lessen the number of attacks; while strychnia, valerianate of quinia, and other agents have all alike failed to afford relief.

I made many experiments with a view to cutting short the fit by interfering with the precedent local spasm; but neither blisters along the nerve-tracks, which are not tender, nor a ligature tightly applied, proved of any use. I then gave the patient a drachm of chloroform in a phial, directing him how to inhale it from a handkerchief, but soon found that he was unable to inhale enough of it to serve his purpose. As a last resort, I gave him in a very small phial three or four drops of nitrite of amyl, and showed him how to inhale it by putting the open phial up one nostril while with one finger he closed the other and then made a few full inspirations. The first attempt failed, because, as he said, the spasm of the left limb made him nervous. On the second occasion he began to breathe it the instant the fingers twitched, having pulled the cork of the phial with his teeth. In a few moments he felt his face flush, the carotids beat violently, his head felt full, and, the spasm ceasing, the attack at once, and for the first time in his experience, was cut short. Four days later he thus cut short another attack; and the experiment has since succeeded in eleven fits, and failed, from too late use of the nitrite, in two. More-

over, the attacks have lessened in frequency, and now come on only once in ten or twenty days. Not only is there no evil effect from the drug, but his memory has improved. He is again taking bromide of lithium.

The case above quoted has since then continued to improve. During the last two years and a half he has had only seven fits, the last being nine months ago. I said seven fits, but in reality only one fit, all of the others having been cut short by the nitrite. A year ago he ceased to employ any bromide, and has been since then using only phosphorized cod-liver oil with strychnia.

Since this case demonstrated for me the remarkable power of this agent to check spasm, I have given it for that purpose a number of times, its value being limited by the rarity of cases in which there is time to secure its full inhalation. In some of my examples the chance of using it has been occasional only, not all of the attacks affording the time needed to secure its value.

J. C., æt. 32, was a good case of this. He had fits about once a week. The persistent use of thirty-grain doses of bromides kept the case in control; but two or three days' omission of this agent was sure to bring about a return of the attacks. His fits came on with a violent spasm of the thumb of the right hand. In most instances they became general too rapidly to admit of interference, but perhaps once in three or four times there was at least a minute of painful spasm of the right member before the loss of consciousness. On four occasions this man was able to use the nitrite, and in each case the fit was aborted.

In both of these cases the warning was in the form of a commencing unilateral spasm. In the following case there was a gastric aura which preceded the fit by an interval so long as to enable the sufferer to inhale the nitrite.

Miss E., æt. 26. Has had epilepsy seven years. Her whole history it is needless to relate. About one minute before the fit comes on, Miss E. has a sense of what she calls "goneness," at the epigastrium. This sensation passes into nausea, and apparently the fit interferes with the consequent vomiting which very rarely follows.

This form of aura is certainly rare. In a single case, during the war, I saw an epilepsy in which emesis, lasting half an hour, preceded the fit. It was cured by full doses of emetics given promptly at the moment nausea was felt. In Miss E.'s case the fits have gradually lessened in number and severity under the use of full doses of nitrate of silver. The nitrite of amyl instantly arrests both the nausea and the subsequent fit; but the sense of fulness in the head so alarms Miss E., who is a highly nervous and emotional person, that she is very averse to using it.

The following case, which, apart from the use of amyl nitrite, is one of the most remarkable known to me, was reported by my former clinical assistant, Dr. Wharton Sinkler, in the *New York Archives of Medicine*; but as these were seen by but few, and had a brief existence, I make no further apology for quoting enough of it to show how valuable the nitrite of amyl may be during the epileptic state.

James M., æt. 24, single. November, 1871, fell ninety-five feet, and had fractured ribs, dislocated ankle,

and fracture of the lower dorsal spine. Unconscious one week. Subsequent palsy of legs, and insensibility. He was five months in this state, and had all of this time incessant headache; then he began to have convulsions, and lost hearing and speech.

When he entered the Infirmary for Nervous Diseases, he walked on crutches, but the left leg was palsied totally and much contracted. The tongue and velum were paralyzed, and he was deaf and speechless.

On the fourteenth day after entering, he had a fit, and they became almost incessant. Blood was taken from his neck, and almost at once hearing came back, but the fits, which were violent, continued.

Nitrite of amyl was now used. It checked a long fit instantly, and after this it was given whenever a fit took place and it could be used in time. In every instance it aborted the fit.

It is needless to say more, save that he became, under various treatment, a strong and really quite vigorous man, able to do a hard day's work.

With this case I close my evidence as to nitrite of amyl in epilepsy. I have never seen it fail where there was time to use it. Last week I suddenly checked with it a fit coming on in my office, and a few months ago had the chance of exhibiting to those present at my clinic its capacity to stop for hours the convulsions of tubercular meningitis in a child.

From what I have seen of this agent, it does not seem to possess, in most cases, any capacity to lessen the probability of a return of the fits; but of its power to arrest the actual convulsion there can be no doubt. As I have already mentioned, I asked Dr. William Jenks to test the nitrite in puerperal convulsions. His evidence as to this point still awaits confirmation by other observers.

I have spoken of the use of the nitrite in the convulsions of tubercular meningitis. I have not yet used it in forms of spasms from peripheral irritation in children, but it would be, I should think, a safe and a ready agent. Neither has it been as yet employed in the horrible convulsions of uræmia.

Before passing from this subject, I am tempted, at the risk of some detail, to speak of a case which is remarkable for the fact that the patient is liable to several, at least three, forms of attack, and that the nitrite while it checks one of these does not seem to affect the second form, and as to the third, far from relieving, only makes it worse. This case has never been published, and I do not hesitate to give it in full, since it is of extreme interest, and distinctly illustrates the possibility of a patient being subject at one time to attacks involving anæmic states, and at another to those which are attended with opposite conditions.

The patient is a cultivated and energetic clergyman, æt. 35, a resident of a neighboring city. He is free from obvious physical disease, and, despite his disorder, is capable of doing, and does do, an abundance of work, involving sometimes severe taxation of mind and body. There is some doubtful evidence as to a sunstroke in his later boyhood, but his first attacks of *petit mal* seem to have come on during the war, while in service with the militia, —known as the six-months' men. At this time he was physically over-taxed, and was greatly exposed

to the summer sun, and slept at night without shelter. I shall leave his graphic statement of his case to tell its own very interesting story.

DR. S. WEIR MITCHELL:

May 21, 1873.

MY DEAR SIR,—I have been troubled for some time past with certain seemingly nervous attacks, the precise character of which, however, I fear it may be very difficult for me to explain, inasmuch as it must always be necessarily hard accurately to describe our feelings in words. But, that I may be able the more clearly to set before you the symptoms accompanying them, I have taken the liberty, simply for my own convenience, of dividing them into several classes, each of which seems to me to have its own peculiar characteristics.

1. Those which have come to be most serious with me, I have learned to denominate as attacks of forgetfulness. My first feeling when one is coming on is of severe oppression across the chest, which sometimes makes it very difficult for me to breathe, and always causes me at once to try to get into the fresh air. This I seldom accomplish, however, as the oppression is almost instantly succeeded by a nervous feeling which creeps over my whole body, and seems to change all the conditions of my existence. I unconsciously move my mouth as if chewing, and sometimes will also grit my teeth. The things around me seem to be moving, and, if I am reading, the book will appear to be going from me, when at once I feel as if all must be a dream, though well knowing at the same time that it must be reality. Then everything seems to leave my memory, and I keep continually striving to connect my thoughts with some event in the past, which seems to be hanging over me, but which I cannot yet recall. Indeed, my whole state of mind at such a time may be best compared to the feelings of one suddenly awakened out of a sound sleep. He cannot catch hold of the dream which seems to be quickly passing from him, and at the same time he cannot yet appreciate the state of consciousness into which he has so suddenly awakened. And thus unable to realize his surroundings, and equally unable to grasp the quickly-fading past, he remains in that disagreeable intermediate state, so to speak, which each one of us has at times experienced.

Now, just so it is with me in these attacks. There is always something going from me which it is impossible for me to recall, and, at the same time, an inability to realize the actuality of my surroundings, while through it all, the fear of some impending catastrophe seems to be hanging over me. This fear seldom goes with the attack, and sometimes, if the attack has been a severe one, will haunt me for three or four days afterwards.

During these attacks I can walk, talk, or use my hands, though everything I take hold of has a strange feeling to my touch. They last generally from two to four minutes; when a considerable belching of wind takes place, and immediately things begin to assume an appearance of certainty about me. But then a violent perspiration pours forth from my forehead, and a feeling of extreme prostration and weakness in the knees comes over me. The past which had gone from me, however, only returns to me by degrees, and some things which have thus faded from my memory never return. For example, books which I have read previously, and even marked and made notes upon, may be taken up by me afterwards as entirely new books. Sermons which I have written with considerable care may be read by me as productions which I had never seen before, and different cities or places may be visited as entirely new sights; while, on the other hand, there are things which I will continue to remember with even more than ordinary distinctness; and books that I have read and sights that I have seen years ago seem to have an equally strong hold upon my memory.

I can give no rule for that which I forget and that which I remember. The first of these attacks which ever came to me occurred in the summer of 1863. I had gone out with the militia at the time of the Gettysburg raid, and such was the extent of the forgetfulness caused, that at the time I could not recall where I was and how I came to be there, and many of the incidents and places of the campaign, fresh in the minds of my companions, have ever continued to be an utter blank in my memory. I may add that we were without tent-shelter, and that I was thus exposed both day and night.

2. The second class of attacks I would denominate as paralyzing. They come on very much as the others, but more suddenly, and the feeling of oppression in the first is rather one of hollowness in these; then at once my right hand becomes fixed across my breast, and I lose all control over my words. My mouth moves even more than in the other attacks; and while I can enunciate, yet I am unable to converse, as I cannot recall even the most familiar words or forms of expression that I may endeavor to. The same feelings of uncertainty usually surround me as in the others, though by no means as severe. But no perspiration or such extreme weakness follows, and the general after-effects, though of the same nature, do not begin to compare in their severity with those of the former. The signal for the discontinuance of these attacks is likewise a belching of wind, and indeed this is the case with all of them, whatever be their nature. This class of attacks does not date back over a year.

3. Both these classes of spells may occur at night, and, unless I am awakened by some one, I will generally sleep through them. But I would immediately awaken any one who was near me, by the peculiar smacking of the mouth and gritting of the teeth to which I have alluded. This does not date back over six months.

4. Flush attacks also come upon me rarely. They commence as though I were going to have a severe attack of forgetfulness, but seem to be turned off sometimes by the power of my will, and sometimes by the mere belching of wind, while others culminate only in a severe perspiration.

5. Ordinary attacks of dizziness are common to me, though without any of the feelings or effects which accompany any of the former attacks. Yet they are sometimes so severe that in my walks I must sit down, or go up to a store-window where I can stand still, have something to hold on to, and shut my eyes. These are generally controlled by an effort of the will if taken in time.

6. Scarcely a day passes that I do not have at least one spell of double sight; and in analyzing such double sight I have found that the false image is made by the right eye, and seems to fall from one to six inches above the object. I always have spots in front of the right eye, and which sometimes seem to form themselves into an image of the eye about one foot in front of it. These three classes of attack (4, 5, 6) date back from twelve to fifteen years.

7. I have considerable and severe pain through my right eye. It generally begins with a severe headache in the early morning, which by ten o'clock has entirely settled in the eye.

I have been troubled with this eye-ache for fifteen years, and it was wont to come regularly every week on Sunday, though lately it has been far less frequent, and very irregular in its return. It has not seemed to have any connection with my other attacks until recently; but now, when an attack comes on while I am suffering from pain in the head or the eye, the pain, be it ever so severe, will leave me during the continuance of the attack.

Apart from these troubles, I enjoy very good health,

though I always have an excess of wind in the stomach and bowels, and am continuously afflicted with a severe catarrh in the head, and considerable thick phlegm. The raising of wind, as I have said, often prevents the culmination of an attack. I have no headache with the exception of that spoken of, which is a beating one, never lasting beyond ten or eleven o'clock in the morning.

Despite the existence of stomachal symptoms, no amount of attention to the stomach and no form of diet seems to make much difference in his attacks. I have all along regarded his case as allied to epilepsy, and was glad to find that Dr. Hughlings Jackson, who has seen him, shared this opinion. In its favor is the fact that the bromides are capable of giving him great immunity from the fits, but when used in the full doses required they rapidly enfeeble him, and very soon weaken his memory, so that they have to be used with the greatest caution, and guarded by the constant employment of arsenic. The eye-ground presents no peculiarities. He speaks of several forms of head-trouble. In the spasmodic attack the right thumb is first turned inwards; then the fingers, and lastly the wrist, are forcibly flexed. Rarely the neck is twisted, and more rarely the right face. This form of fit is cut short by the nitrite. As the face flushes the attack passes off. The spells of pure giddiness have been frequent of late. They come on suddenly, and there are none of the strange mental conditions which attend the other spells. Now, in these vertiginous fits, the nitrite if used early only hastens the culmination of the trouble, and, he believes, greatly intensifies it.

I have made frequent use of nitrite of amyl in a variety of forms of disease, chiefly spasmodic, some of them hysterical, and some of indeterminate birth and relationship.

Its influence over cases of hysterical angina is as well marked as in those of men, or in non-hysterical attacks of this disorder. I have twice employed it in forms of disease which are akin to angina, are not infrequent, but lack a distinct name.

Here is one which may pass as an illustration.

A middle-aged lady, after many and grave trials during the late war, began to suffer from occasional attacks which came at any time in the day, held no relation to conditions of the stomach or uterus, but were at last most frequent and distressing. A sense of fullness at the epigastrium announced the attack, and from the stomach a sort of aura, accompanied with a feeling of panic and terror, passed up into the head, with intense pain in the right neck and face, the infra- and supra-orbital region, and at last a few moments of deadly pallor ended the attack, which occasionally wound up with nausea and rarely with emesis. There was no irregularity of the heart, no pain in the arm, only a slight quickening and enfeeblement of pulse towards the close of the attacks, which usually lasted from one to five hours, and when I saw her were of daily occurrence. After a trial of many means, I at last used the nitrite of amyl. The effect was singularly happy, and it was very rare that it failed to break up and dispel the trouble. After a time I gave her a small vial of the nitrite, and this she continued to use, her attacks growing less frequent and less severe. When I heard last from her, they were still under control of the nitrite.

I come now to speak, and with rather more hesitation, of the use of this agent as an aid to the diagnosis of certain forms of cerebral disorders.

Those who see much of neural diseases meet very

often with cases of head-troubles in which there are attacks of vertigo, or disturbed equilibrium, or mere sense of fullness with or without mental disorder. Occasionally these troubles are plainly not epileptic. Sometimes they are either epileptic and distinctly so, or else are the far-away beginnings of that malady. Sometimes a therapeutic diagnosis is possible, and the mere fact of the bromides controlling them may, when taken with the symptoms, clearly settle their nature. But very often our suspicions are in favor of their being purely vascular disturbances of congestive type, and then I think that the nitrite of amyl may prove serviceable in settling the question; since in such cases the inhalation will sometimes recreate briefly the train of symptoms, so that they are at once recognized by the patient. This, when it occurs, is fairly conclusive as to the attacks having been truly congestive in character. The negative has also its value. Personally I have obtained useful help from this means, but I look upon the whole matter as one which it is well to present to the profession as worthy of study, without at present claiming for it any very great utility.

I give below cases to illustrate the use of the nitrite in diagnosis:

E. L., accountant, a very nervous and irritable person, æt. 29. Has spells, two or three times a week, in which he is said to lose consciousness, without any co-existent spasm. On other occasions the trouble does not go so far as this. Has been told the attacks are epileptic. On inhaling nitrite of amyl, he said at once, "That is the kind of feeling I have in my attacks." Then he asked to have the inhalation repeated, and again recognized the symptoms as like those he had had. I came soon, thus aided, to understand, with no doubt in my mind, that his fits were coincident with relaxation of the arterioles. He was rapidly cured by full doses of digitalis with general tonics and cold shower-bath.

I. C., æt. 40, lawyer. This gentleman has vertigo, in which external objects float around him, from right to left. He does not know if he flushes in the attacks. I can find no reason for them in the state of any extra-cranial organ; nitrite of amyl causes in him the usual symptoms, but no trace of vertigo. This is a fair type of many cases in which I have used nitrite of amyl. It never reproduces the vertigo.

Robert H., æt. 38; a master of an oyster-boat; had a slight sunstroke in August, 1873. Ever since, he has a great deal of vertex headache, with now and then severe attacks of general headache. I was inclined to believe that the vertex pain was due to subacute meningitis. It was suddenly made worse by nitrite of amyl, to which he was very sensitive. I have said that it was made worse; it was in fact increased by this drug to such a degree for a few minutes as made me regret my experiment.

I might multiply these examples. In some cases the nitrite has failed to help me, in others it has returned a useful negative, in others a still more valuable affirmative. I shall add but a single case.

Mr. Ph. C., æt. 43, had, ten years ago, a malarial fever, followed by a sharp attack of cerebral peripheral meningitis. From these diseases he recovered, but has had ever since, at brief and briefer intervals of late, left frontal headaches. Within six months these are accompanied with certain very curious disturbances of speech, which last for but a few hours during the height

of the headache. At these times he pronounces certain words as if the first letter or first syllable had no existence. Thus, a very bad dog would become a *ery ad og*. Sometimes he adds the first syllable of one word to the next, and its first to that of the preceding word. Thus, a bad dog would become a *gad bog*, and so on. In these attacks the left temporal artery throbs visibly and most remarkably, but the face does not flush. The attacks occur always after dark, but when I gave him nitrite of amyl in my office I suddenly reproduced the headache and the train of peculiar lingual phenomena. He said *top* for stop. *Hat turts*, that hurts. *Thy med robs*, my head throbs. The effect passed off suddenly, and his usual control of language returned.

As to this case there could, I think, be little doubt that the cause lay in an over-readiness of the vessels of the left anterior cerebral lobes and subjacent meninges to fill up with blood, and so for a time to disturb the nutrition and function of the parts concerned.

I find physicians very timid as to this remedy, but, after much and long use of it, I have altogether lost the dread of it with which I began. I would suggest that in syncope and in hysterical convulsions it might well repay a trial, and that possibly in the cerebral symptoms arising from shock it may also prove of value, and should be essayed in the cold stage of ague.

ON THE DETECTION OF ORGANIC MATTER IN DRINKING-WATER.

BY CHARLES MCINTYRE, M.D.

AS the time is approaching when the medical societies in the several counties of the State will prepare their reports to the State Society, and since a resolution, adopted at the Easton meeting, instructs the county societies to incorporate in their reports certain facts as to the condition of the potable waters when in the vicinity of graveyards,—among other things, as to their purity,—a few words on the examination of such waters may be of interest.

A full examination of the character of a potable water as to its organic constituents is, perhaps, one of the most difficult problems in the ordinary run of analytical chemistry. There is organic matter decomposed, decomposing, and ready to be decomposed, to be looked for; a discrimination to be made between organic matter of all grades, from the perfectly inert up to the pestilence-producing; and, more, these frequently can only be recognized by the products of decomposition, usually the same from all classes mentioned.

R. Angus Smith (*Chemical News*, xix. 278) thus classifies the organic material:

1. Organic matter decomposed or putrid.
2. Organic matter readily decomposed, and probably ready to become putrid.
3. Organic matter slow to decompose.
4. Recent organic matter.
5. Old organic matter.
6. Animal organic matter.

While this is the case, yet, for a physician's practical purposes, there are a few tests which would put him on his guard, and at least give more accu-

rate results than relying solely upon the presence of ammonia, as recommended in connection with the resolution of instructions.

It is foreign to our purpose to discuss whether, under the conditions of the resolution, ammonia would be always present if the water was contaminated; but, since an examination is in contemplation, we wish to suggest the method of obtaining more reliable results.

The tests described are all in use by experts in water-analyses; they have been altered, in some cases, in the details, so that they can be applied by any physician with an ordinary amount of apparatus. Of course, only *qualitative* examinations can be made, and approximative results obtained. While these, for purposes of scientific investigation, or even for a full report on the wholesomeness of any water, would be nearly useless, nevertheless, for the purposes indicated they are of more value than the more delicate tests or the *quantitative* determinations, since they can be used on ordinary occasions, while the latter would require the special apparatus of a chemical laboratory with the skill of a professed chemist. This distinction is insisted upon, because the whole subject of the determination of organic material in water is, if not in midnight gloom, only in the morning twilight; and so much has been written purporting to give accurate results while only employing these approximate methods, that the not yet cleared-up subject has been made rather the more misty by such work. But to plunge *in medias* without further preface.

We may have organic material—

I. As to its derivation: *animal*, or *vegetable*.

II. As to its condition: *not decomposed*, or *decomposed*.

a. If not decomposed, either (1) in the same form as it exists in the organism, or (2) changed into some complex organic substance.

b. If decomposed, it may exhibit any of the products of decomposition down to the purely inorganic,—e.g., carbon dioxide, nitric acid,—and these may be present along with organic material, which may escape detection.

III. As to its effect: *deleterious*, or *harmless*.

This classification is sufficiently extended for our purposes.

If the organic material is of animal origin, the nitrogen compounds will ordinarily be more abundant. These are the compounds which are supposed to exert the greatest influence in causing the water to be unwholesome.* Unfortunately, most of the methods will not enable us to tell of the source of the organic material, and in doubtful cases it may be difficult to decide as to the condition of the water.

If a quantity (f3viii) of water is evaporated care-

* The presence of ammonia, or even, perhaps, of albuminoid substances (not readily putrescible), does not of necessity render the water unfit for domestic purposes, or even prove the presence of recent organic material. A case in point is mentioned by R. Angus Smith (*loc. cit.*, p. 281), of waters from the hills of Scotland, Wales, and elsewhere, showing evidence of large quantities of ammonia, and even, according to the later researches of Prof. Wanklyn, of what he terms albuminoid ammonia, more being found in the water from these bare hills than from the rich plains. Yet there is no apparent source for injurious organic matter. This is only another instance of the doubts and difficulties of water-analysis.

fully to dryness in a clean porcelain or glass vessel, and then heated gently, the blackening of the residue will indicate the presence of the more stable organic compounds, which will all disappear by a further application of the heat with access of air. If during this latter operation there is any deflagration or rapid combustion, it indicates the presence of nitrates in the water. A very rough approximation of the amount of this organic matter can be made by weighing when dry, and again after it has been burned off. There are very few waters so free from organic matter as not to leave a blackened residue, while at the same time it would be possible to have a water rich in organic material which would leave little or no char. This test, then, is of use when the amount left is greatly in excess of the char from comparatively pure water.

Allow another portion of the water to stand in a warm place, exposed to the light, for several days. Should the water become putrid or show the presence of animal or vegetable growths, either to the naked eye or by the aid of the microscope, there should be grave doubts as to the fitness of the water for domestic purposes,—the gravity of the doubt of course depending upon the extent of these conditions. It is asserted that at times organic matter is contained in water in such a condition as not to respond to the ordinary reagents until after it has undergone some decomposition. Consequently, in a suspected water, if no reactions can be obtained in the fresh water it would be advisable to let a portion stand as above, and then test.

The presence of ammonia, nitrous and nitric acids, any or all, indicates the presence of nitrogen in the water. It is possible, however, for this nitrogen to have its origin in inert organic material, or even to have an inorganic origin, and, hence, exercise no deleterious effect upon the water. Their presence is suspicious, and should always be looked for.

Nessler's reagent is perhaps the best test for ammonia. This reagent, the preparation of which is given in any text-book on analytical chemistry, and also in the Transactions of the Medical Society of Pennsylvania, x. 19, may be extemporaneously prepared by adding to a solution of potassium iodide (1 pint of salt to 20 pints of water) a solution (1 to 16) of mercuric chloride (corrosive sublimate) until a permanent precipitate is produced. Then add about twice the volume of liquor potassæ, let stand for a few days, and decant from the sediment. This will be delicate enough to detect an exceedingly small quantity of ammonia; a brownish precipitate or coloration being formed, depending on the amount of ammonia present.* If there is much testing to be done, the reagent had better be prepared according to some formula.

Nitrous acid is readily detected by its power to liberate iodine from potassium iodide, which is manifested by its action on starch paste. Prepare some starch paste, add about one-eighth the volume

of the solution of potassium iodide, acidulate the water with hydrochloric acid, or, preferably, sulphuric acid, in order to liberate the nitrous acid if it is combined as a nitrite, and then add the mixture of starch paste and potassium iodide. The immediate formation of the blue iodide of starch will indicate the presence of nitrous acid. It is hardly necessary to add as a caution the necessity of using pure acids and of having clean vessels; a failure to have either would render the accuracy of the results open to doubt. To test for nitric acid, the unignited residue had better be employed. Dissolve some morphia, or, better still, brucia, in a drop of sulphuric acid, on a piece of white porcelain; it should develop no color; if now a few pieces of the solid residue be added, the presence of nitric acid will be shown by a rose-red coloration in the former instance, or a deep blood-red if brucia has been used.

In many cases the organic material is readily oxidized by means of potassium permanganate. Render the water slightly acid by means of sulphuric acid, and drop a few drops of a solution of potassium permanganate; the solution becomes decolorized, owing to the permanganate giving up its oxygen for the oxidation of the organic material. This test, while not a reliable one when used with so few precautions, may, nevertheless, act as one witness among many to prove the character of the water.

When the water may be contaminated with sewer-refuse, there is a large increase of the alkaline salts, notably common salt,—sodium chloride,—the chlorine of which can readily be detected after rendering it strongly acid with pure nitric acid, by a solution of silver nitrate, a white curdy precipitate being formed. Since this salt is normal in small quantities in most waters, the resulting precipitate should be quite decided to indicate any sewage-matter.

There is one other test, which, while it requires more laboratory manipulation, should be noticed, since it attempts to give us intelligence of animal matter while still in an albuminoid condition. This is the test known as Chapman and Wanklyn's test (*Jour. Chem. Soc.*, xx. 445, 591), and depends on the principle that a solution of caustic potash and potassium permanganate is able to cause the nitrogen of albuminoid substances to enter into combination with hydrogen and form ammonia, which then can be detected by Nessler's reagent. To apply the test, it is first necessary to remove all ammonia in the water, as well as urea, which readily changes into ammonia; this is done by distilling a portion of the water until portions of the distillate give no reaction with the Nessler solution; then add a strong solution of potassium hydrate and a solution of potassium permanganate; collect the distillate, and examine again for ammonia. Its presence indicates albuminoid material in the water.

An examination of this sort, while it takes but a comparatively short time, may be of great value in investigating the source of a certain class of diseases. The necessity of pure drinking-water is so generally admitted, and the grave results from using impure water have been so fully written upon

* Instead of attempting to describe the reactions, it will be better for the experimenter to make a few preliminary tests with waters in which have been placed ammonia, nitric acid, albumen, urea, or whatever is to be looked for, should he not be already familiar with the reactions.

of late, that, even if it were not foreign to the purpose of this paper, it would be a vain repetition to dwell upon them.

Should such an examination be undertaken by any of our county societies for their next report, I would suggest the desirability of tabulating their results, in order to make them useful for comparison. A uniform method of reporting would aid this; and I would offer the following, perhaps as convenient as any.

Rule a sheet of paper so as to form ten columns. In the first, give the place and date of collecting the water; in the second, the topographical and geological conditions required by the resolution. The third is devoted to the physical appearance, taste, etc. In the next six place the results of the testing (no column is given for Wanklyn's reaction); while in the remaining column the other information as to zymotic diseases, and whatever information is necessary to be given, along with the name of the examiner, can be included under the heading of remarks, thus:

WATER FROM.	TOPOGRAPHY AND GEOLOGY.	APPEARANCE.	EVAPORATE TO DRYNESS AND IGNITION.	PUTRESCING TEST.	POTASS. PERMANGANATE.	NESSLER'S TEST.	STARCH AND POTASS. IODID.	MORPHIA OR BRUCIA.	REMARKS.

NOTES OF HOSPITAL PRACTICE.

JEFFERSON MEDICAL COLLEGE.

CLINIC OF PROF. S. D. GROSS.

Reported by D. C. ALLEN.

STRANGULATED FEMORAL HERNIA—SYPHILITIC CARIES OF THE LEG—STONE IN THE BLADDER.

CASE I.—The first case, gentlemen, that I shall bring before you is a woman, aged 40, suffering from strangulated femoral hernia. She has been troubled with the affection for six years, a truss having been worn during this time. Thirty-six hours ago she was seized with severe pain in this situation, and it was discovered that the bowel had become strangulated. An attempt was immediately made at reduction, but was not successful. The patient was sent to bed, an anodyne given, and ice-bags applied to the groin. After some hours the taxis was again carefully tried, but, as before, reduction could not be effected, and an operation is therefore required without delay. This form of hernia is by far more frequent in women than in men, while inguinal hernia is more common in males. Femoral hernia may be mistaken for various affections, from which it is of great importance that it should be distinguished. The most common of these are inguinal hernia, enlarged lymphatic glands, and psoas abscess. Ordinarily but little difficulty occurs in regard to the distinction between femoral and inguinal hernia, remembering that in the former the neck of the tumor is below Poupart's ligament, while in the latter it is above that line. From an enlarged lymphatic gland or a psoas abscess, femoral hernia can generally be readily distinguished by a careful examination and an inquiry into

the previous symptoms. The constriction in this form of hernia may take place either in the true hernial sac, or at the internal or external femoral ring. During the operation the patient is anæsthetized, and the thigh is flexed upon the pelvis and inverted in order most completely to relax the fascia lata in the region of the groin. I make a vertical incision three inches in length, by pinching up a fold of skin directly over the tumor, transfixing it, and cutting from within outwards. The skin and cellular tissue being divided by this incision, with great care I divide layer after layer upon the grooved director, pushing aside the lymphatic glands to avoid wounding them. The anterior sheath of the vessels is now divided, and, passing my finger up, I search for the seat of the stricture, which is found to be at the lunated border of the external ring. A probe-pointed bistoury, guarded by the finger, is passed up to the constricting band, and cutting upwards and slightly inwards the stricture is divided. Ascertaining that the bowel is in a fit condition to be returned, its contents are gently squeezed out, in order that it may be the more easily pushed back into the abdomen. Although the constriction is completely severed, freeing the strangulated bowel, yet the latter cannot be returned into the abdominal cavity, owing to its firm adhesion to the inner surface of the sac. This condition is due to the long standing of the affection, and constitutes an irreducible hernia. The wound is carefully approximated by sutures, and a compress and bandage applied. After all such operations a truss must be worn. During the after-treatment the patient must be kept at rest, anodynes given, and the bowels locked up for some days.

Case II.—The second patient is a girl, aged 21, laboring under syphilitic disease of the right leg, presenting itself in rupial ulceration of the skin and extensive necrosis of the tibia. Five years ago she had manifestations of the specific disease, and two years later, well-marked constitutional symptoms were developed. Her mother has suffered from the same disease, and the affection in this case is doubtless transmitted.

The lower two-thirds of the leg, and also the foot, are so extensively diseased that amputation is the only measure likely to be productive of any benefit. It is a matter of much moment to decide whether amputation shall be performed above or below the knee. On examination, the upper third of the leg is apparently sound, and hence I shall remove the limb a little below the junction of the latter with the middle third. The patient is under an anæsthetic, and Esmarch's bandage is applied from the foot upwards to force the blood up into the body, and the elastic cord applied to arrest hemorrhage during the operation. I shall amputate by the circular method. The integument is divided down to the aponeurosis by a circular cut, and dissected back two and a half inches. Then the muscles are divided in a similar manner down to the bone, on a level with the reverted integument. The muscles are separated from their connection with the bone for about an inch and a half, and forcibly retracted. The saw is now applied as closely as possible to the soft structures, and held perpendicularly, dividing first the fibula, and lastly the tibia. The bones are trimmed off smoothly with the bone-pliers, and the bleeding vessels secured by ligatures. The wound will be allowed to remain open for two hours, when it will be approximated with sutures and adhesive plaster. The patient, being weak and much reduced, will be put upon supporting and invigorating treatment, and, after she has sufficiently recovered, specific remedies will be employed.

Case III.—The next case requiring our attention is one of urinary calculus in a boy 13 years of age. He has had trouble in his bladder since he was two

years old, and for the last six years has had the rational symptoms of stone, such as incontinence of urine, pain in passing water, frequent micturition, and interruption in the flow of the urine. To determine with certainty the presence of the stone, a sound is introduced, and immediately comes in contact with the foreign body, which is distinctly heard and felt. The patient was prepared for the operation by administering, on the evening previous, a brisk purge, to clear out the alimentary canal. The urine has been retained for several hours, to distend the bladder moderately, to prevent injury to its walls, and to facilitate the extraction of the stone. An anæsthetic is given, the thighs are flexed upon the pelvis and separated from each other, and the buttocks brought down to the edge of the table. The staff is introduced, and the curved portion lodged in the bladder is made to bear slightly to the left side of the perineum, and hooked up closely against the pubic symphysis. Oiling the index-finger, it is passed into the rectum to promote contraction of the bowel, rendering it thus less liable to be wounded by the knife. With a slender, sharp-pointed bistoury I make the incision by entering the point at the raphé on the left side of the perineum, an inch above the margin of the anus, carrying it obliquely downward and outward a little below the level of the tuberosity of the ischium, and a little nearer to this point than to the anus. Guarding the knife with my index-finger, I extend the incision deeper, dividing some of the fibres of the transverse perineal muscle and a portion of the triangular ligament. The membranous portion of the urethra is exposed, and, feeling for the groove in the staff, the knife is passed into the bladder, dividing a portion of the neck and prostate gland. As soon as the knife enters the bladder, the urine flows out. The opening into the bladder through its neck and the prostate gland is enlarged, if necessary, with the finger; passing my finger into the bladder, I feel the stone. The staff is now withdrawn, and, introducing the forceps, the calculus is grasped and extracted. The bladder is washed out by injecting into it a full stream of tepid water from a large syringe. The patient will be placed in bed upon a draw-sheet, and, if he suffer much pain, an anodyne will be given. As the lad is very weak, and much reduced from protracted suffering, quinine and iron, with the most generous diet, will be ordered.

PHILADELPHIA HOSPITAL.

SERVICE OF DR. H. C. WOOD.

DIABETES INSIPIDUS—RECOVERY.

CHARLES T., æt. 55, a painter by occupation, entered the hospital on the 15th of September, 1874. At the time of his admission he complained of little but an all-pervading sense of lassitude and debility, which had been growing upon him for a year or more, and which finally had obliged him to throw up his occupation and enter the hospital. Upon investigation, the man was found to be of an extremely nervous and excitable temperament, but no symptom of importance was discoverable, except that he was daily passing an amount of urine much above the normal. The patient had first noticed this increase in his urine during the summer of 1873, and was inclined to ascribe it to drinking cold spring-water while much exposed to the sun. Repeated careful examination failed to show either albumen or sugar in the discharge. In other words, the case was one of diabetes insipidus.

The following table shows the date and the number of ounces of urine passed in twenty-four hours, and the treatment. The diet was uniform.

DATE.	URINE, OUNCES.	TREATMENT.
Sept. 15	168	Gallic acid, gr. x, t. d.
" 17	172	
" 25	160	Gallic acid stopped. Ordered assafoetida, gr. x, t. d.
" 30	168	
Oct. 3	180	Assafoetida stopped. Opium, gr. ss, t. d.
" 6	180	
" 9	174	
" 10	190	
" 11	178	
" 12	184	Ordered zinci valerian., gr. i; opium, gr. ¼, t. d.
" 13	160	
" 14	140	
" 15	100	
" 17	96	
" 18	56	
" 19	48	
" 25	46	
Nov. 1	43	The man's general health very much improved.
" 13	43	The treatment has been the same since October 12. All drugs discontinued.
" 30	44	Man discharged well and hearty.

TRANSLATIONS.

THE CYANIDES IN ACUTE RHEUMATISM.—Dr. A. Luton, of Rheims, publishes in the *Bull. Gén. de Thérap.*, January, 1875, an article on this subject. He begins by alluding to the innumerable specifics which have been vaunted in acute rheumatism, their very number suggestive of want of faith in any or all of them.

He specifies, in particular, propylamine and trimethylamine, as well as colchicum. Of the latter he says that it is the best remedy heretofore known, and were he to cease using the cyanides in rheumatism he should certainly return to colchicum. Its full benefit, however, is not gained until it is pushed to an almost semi-toxic extent. The factitious production of a gastrointestinal catarrh, which is the effect of the use of this remedy, is, however, nothing in comparison to a disease which threatens existence not only at the moment but at any future time.

After describing his method of administering colchicum, Dr. Luton goes on to say that, in his opinion, the cyanides, particularly those of zinc and potassium, are destined to replace this drug in the treatment of rheumatism. He then gives a number of illustrative cases in which these cyanides were used with the happiest effect. The cyanide of zinc is a white powder, insoluble in water, easy to form into pills or to administer in suspension in some mucilaginous fluid. It possesses neither taste nor odor, and may be given without the patient's knowledge. In spite of this, its physiological and therapeutic properties are real. It doubtless dissolves in the gastric juice. The doses in which Dr. L. gives this cyanide vary from three-fourths to one and a half grains, two grains, or even three grains, in a single day. The cyanide of potassium, pure and well prepared, is perhaps to be preferred, he thinks, to the salt of zinc, on account of its evident activity. In mixture he has given it in the dose of one and a half grains a day. On account of its disagreeable taste and the rapidity with which it alters in solution, it is best administered in the form of pills, coated with silver. It is not advisable to go beyond two grains per day; though cumulative effects are not to be feared.

At a certain point the physiological effects are produced: frontal headache, vertigo, nausea, some colic, occasionally slight diarrhoea; more frequently the stomach is advantageously stimulated, the appetite improves, and digestion becomes easier. Finally, the cyanides

bring about a certain degree of general sedation, and tend to produce sleep.

"It is certain," concludes Dr. L., "that the cyanides cure acute articular rheumatism, in its original form and in its diverse transformations. It cures by shortening the duration of the disease, and by diminishing the risks of complication. Rapidity is one of the essentials of all good anti-rheumatic medication. Add to this the fact that these preparations are not hard to take, and are *anodyne*, and we fulfil the three great recommendations,—*cito, tuto, et jucunde*." X.

PARENCHYMATOUS INJECTIONS.—A NEW MODE OF TREATMENT OF SYPHILITIC BUBO (Dr. Franz Jakubowits, *Wiener Med. Presse*, Nos. 3 and 4, 1875).—In 1869, Dr. J. advocated the direct use of injections of the iodide of potassium, and claimed that good results were obtained from them in the treatment of inflamed and hypertrophied glandular tissue. Since that time he has extended their use, and has employed them in scirrhus of the breast, hyperplastic struma, scrofulous inflammation of glands, and in buboes of syphilitic origin.

His experience with injections of this salt confirmed the theoretical views which seem to make them applicable; and in syphilis they would appear to be especially indicated, since the remedy acts both locally by inducing resolution, and also upon the entire economy when once absorbed.

I. H. M., a priest, aged 26, in November, 1873, contracted an indurated syphilitic ulcer, which healed after a treatment of six weeks' duration; and on the 6th of January, 1874, the inguinal glands were found to be infiltrated and quite sensitive, and in four days there was a bubo of the size of a hen's egg upon the left side.

Owing to an unusually large number of deaths among the members of his flock, the patient was unable to rest, and the bubo rapidly got worse.

Various resolvents and cold applications were unavailingly used, and at last it was determined to employ parenchymatous injections of the iodide of potassium, with the hope that a speedy resolution might be obtained.

The tumor was at this time as large as a goose's egg, the skin upon and about it inflamed and sensitive, but no sense of fluctuation was experienced upon careful examination. On the 14th, the first injection was made, a solution of fifteen grains of the iodide and five drops of the tincture of iodine in one ounce of water being employed. The injection was made at the most prominent part of the swollen gland, the needle being introduced somewhat obliquely, so as to prevent the entrance of air and to assist in maintaining the fluid in the gland upon the withdrawal of the instrument. After about the fourth part of the contents of an ordinary hypodermic syringe had been injected, there was a feeling of resistance, and the needle was then partially withdrawn and again thrust forward, but in a somewhat different direction. This manœuvre was repeated several times, until the entire contents of the syringe had been injected. Neither blood nor pus escaped from the opening made by the syringe, but traces of pus were noticed on the needle. The patient suffered no pain from the introduction of the instrument, but during the injection complained of a painful increase of tension in the gland. After a short time the wound was dressed with carbolized adhesive plaster, and the patient ordered to spare himself as much as possible and to present himself the next day. In the evening of the same day he came, and stated that although he had been the whole day upon his feet he had felt no pain, and could move with much more freedom. The tumor, upon examination, was found to be harder, and the skin not so red, and less sensitive upon pressure.

On the 15th, a still further improvement was noted, and the injection was repeated in the same manner as before. Two more injections, at intervals of two days,

were made, so that altogether but one and a half grains of the iodide and half a grain of the tincture of iodine were administered. A constant improvement took place, and after eight days there was a tumor of the size of a large nut, which in another week entirely disappeared.

The second patient was a farmer, aged 23, who presented himself on the 6th of October, saying that he had had a bubo for five weeks, which, in spite of all the treatment that had been employed, neither suppurated nor gave any signs of resolution. This bubo was no longer painful, but the man's digestion was beginning to suffer, and he was restless and could not sleep, and had night-sweats. He had been infected with syphilis three months previously, and the primary lesion had speedily healed. Upon examination, a tumor was found in the left groin which consisted of two portions, each of which was as large as a pigeon's egg, the skin over it being livid and thickened, and not movable.

The same mode of treatment was commenced at once, and continued from day to day with progressive improvement, until the operation had been ten times repeated. It is true that this mode of treatment has been used in but few cases, and that a wider experience does not always give the same success as is at first obtained; but still Dr. J. thinks that he is justified in calling the attention of the profession to the striking successes which he obtained in these two cases. W. A.

THE PATHOLOGICAL ANATOMY OF THE INSANE (*Wiener Med. Presse*, No. 3, 1875).—Professor Meynert sustains the view of Baillarger, that certain conditions are found on the surface of the brains of patients with progressive paralysis and mental disturbance, especially a destruction of the superficial cerebral layers with a thickening of the membranes, which is looked upon as an evidence of a chronic diffuse periencephalitis.

He also finds in the substance of the brains of those who have had typical progressive paralysis, with an acute exacerbation of the symptoms, the so-called serous softening of the brain-tissue. This was found, by the microscope, to be an active inflammatory process, and could not possibly be looked upon as a post-mortem change.

The results of such pathological investigations have strengthened him in the opinion which he expressed ten years ago, that the similarity in the changes in the ganglion-cells in the connective tissue, and in the vessels which are found in the brains of paralytics, with the changes in the œdematous zones about acute encephalic deposits in the brains of others with cerebral disease, points to the previous existence of an affection related to encephalitis which has run its course in the brains of paralytics. He has found precisely the same conditions in the atrophied horn of Ammon of epileptics and in the brains of paralytics. He divides these changes into two series: the one an evidence of existing stasis, the second a proof of the solution of pre-existing stasis. By the discovery of the existence of stasis, the process which goes on in the brains of patients who suffer with progressive paralysis is proved to be of an inflammatory character. W. A.

A CASE OF ABDOMINAL TYPHUS WITH ICTERUS (Dr. M. Heilter: *Wiener Med. Presse*, No. 3, 1875).—The patient, a boy of 18, was admitted into the hospital on the 19th of September, 1874, with many of the usual symptoms of typhoid, having also the entire surface of the body, including the conjunctivæ, intensely jaundiced. Death occurred on the 21st, and at the autopsy the glands of the lower part of the ileum were found to be much swollen, and at some points near the ileo-cæcal valve brownish-yellow sloughs were met with. The liver was rather large and relaxed, its structure altered and icteric, and in the gall-bladder there was some brown bile. W. A.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MARCH 6, 1875.

EDITORIAL.

BILLS OF INTEREST TO THE PROFESSION.

THERE are at present before the Pennsylvania Legislature three bills in which the profession is deeply interested, and all of which, we trust, will be acted upon favorably. The first of them is entitled "An Act to Regulate the Practice of Medicine, Surgery, and Obstetrics in the Commonwealth of Pennsylvania." It practically amounts to as follows. Any person who has been in practice in the State for ten years may continue to practise without let or hindrance, but no others shall do so unless provided with a diploma from a chartered institution which does not sell its diploma. Any practitioner not having a diploma shall have the right to apply to any of the medical schools of the Commonwealth for examination, and, if found worthy, shall be granted a certificate allowing him or her to practise. Any person who shall open a transient office, or who shall advertise such transient office or other place to persons seeking medical or surgical advice, shall satisfy the clerk of the quarter sessions that the provisions of the act have been complied with, and shall also take out a license for one year, paying therefor the sum of two hundred dollars into the county treasury. A fine not exceeding five hundred dollars, or imprisonment not exceeding one year, is the penalty imposed for violation of the enactment.

On the whole, we think this bill a very good one, although, of course, we should like to have seen it go further. Believing as we do that a diploma from the medical schools is no guarantee that its possessor is in any degree fitted for the practice of

medicine, we would have preferred a State Board of Examiners before whom every aspirant for practice should appear. As, however, this is a democratic community, we suppose interference with the power of the medical schools to grant the right to kill would not be tolerated, and, not being able to get the whole loaf, let us be thankful for the half of it. The bill will, if enacted and enforced, do away with two great evils,—practising without a diploma, and peripatetic quackery.

The second act has for its object the creation of a State Board of Health, to consist of five physicians, appointed by the Governor with the advice and consent of the Senate, together with the Attorney-General of the State and the Secretary of Internal Affairs. This board is to serve without salary, but their actual expenses when travelling, and the necessary clerical expenses, are to be paid by the State. The Secretary of the Board, who must be a physician, is to be elected by the Board, and is to receive a salary not exceeding three thousand dollars. The Board has also power to expend moneys in special sanitary investigations; but the whole expenses are not to exceed eight thousand dollars a year.

We have not space here to detail the various duties which are pointed out, but the proposed act seems to us an excellent one, and, so far as we can see, good in all its details.

The third professional bill before the Senate at Harrisburg is to "authorize the use of unclaimed bodies of convicts and others for the promotion of the medical sciences." It is quite long, and we have not space for its analysis, but it seems to us very fair and wise in its provisions.

THE WARREN PRIZE.—We would call attention to the advertisement of the Warren Triennial Prize. This was provided for in the will of the late J. Mason Warren, in honor of the memory of his father, John C. Warren. The trustees of the fund are those of the Massachusetts General Hospital, and a committee of the staff of the hospital constitutes the judges. No essays were presented for the prize of 1874, for which year the subject proposed was "The Elimination of Drugs by the Mammary Gland." No special subject is given for 1877, but competitors have the full latitude allowed by the will to choose any subject in physiology, surgery, or pathological anatomy, involving original researches. The only prize as yet taken found its way to this city; and we trust that hereafter the like result will be so common as to be looked upon as a matter of course.

LEADING ARTICLES.

THE USE OF COLD IN FEVER.

NO. IV.

IN concluding this series of brief articles upon the treatment of pyrexia by the abstraction of heat, it only remains to consider the various methods of attaining the desired end. These methods are divisible into two sets: those in which water is brought in direct contact with the person of the patient, and those in which the bodily temperature is reduced by the application of bags containing ice or water.

The first of these general plans is undoubtedly the most efficient, and has been the one generally employed. In selecting a special mode of application, it must be borne in mind that no good is achieved unless the temperature of the body is reduced and *kept down*. The clinical thermometer must always be the guide as to the efficiency of the application, and the latter must be renewed so soon as the fever-heat re-manifests itself. The *cold pack* is the least troublesome, and generally the least disagreeable, of all the methods of applying cold water. Unfortunately, it is not sufficiently powerful to act decidedly upon adults suffering from intense fever. I have seen it time and again fail to make the slightest impression. When it is employed, the bed should be covered with an india-rubber blanket or cloth, the sheet wrung out, not too dry, in water as near 32° F. as is convenient, and wrapped closely round the naked person of the patient. No other covering should be allowed; or, if demanded by modesty, it should consist simply of a sheet loosely thrown over the person. If the patient be enveloped in blankets, all anti-pyretic influence is lost, and the pack soon becomes really a warm sweat-bath. The continuance of the cold pack should vary *pro re nata* from five to ten minutes, at the end of which period the sheet is usually thoroughly warmed. Its power is greatly increased by sprinkling it every five minutes with ice-cold water from the spray-nozzle of an ordinary watering-pot; in this case the application may be continued for a long time, if necessary. The number of packs to be used in the twenty-four hours depends entirely upon the rapidity of rise in the bodily temperature: whenever the latter gets to 102° in the axilla, the sheet should be replaced. If the cold pack in any case is unable to reduce the temperature to 102° F., it should be set aside; indeed, as already intimated, it is not applicable to *adults* suffering from a high grade of fever; in *children* its effects are more pronounced.

The bath is used in various ways, but these may be practically considered as modifications of two, or at most three, different plans: that of the lukewarm bath, used as such, or in the modified form known as the method of Ziemssen, in which the bath is gradually cooled whilst the patient is in it; that of Brandt, in which very cold baths of short duration are given; and that of Currie, in which cold affusions are practised.

The use of lukewarm baths (85° F.) in fever has not

met with much favor. It would appear at first sight that a cool bath would simply require a longer time than a cold bath in order to reduce bodily temperature to the one point. The experiments of Liebermeister have shown, however, that the tepid bath is in no degree comparable to the cold bath in its effects on bodily heat. As illustrative of the inequalities of results obtained by different but apparently equivalent methods of abstracting heat, may be mentioned the fact, apparently proven by Liebermeister, that the influence of two short cold baths at a brief interval is much greater than that of one bath of like temperature whose duration is equal to that of the two short ones. It has also been found in practice that whenever in the adult the fever is high, tepid bathing has very little influence upon it. Such baths may, however, be employed in very feeble persons where the pyrexia is not very marked. Upon children the lukewarm bath is said to produce much more decided effects than it does upon adults.

The researches of Liebermeister indicate that the larger the patient is, the cooler must the bath be in order to influence the bodily temperature. In judging of the effect of a bath, it must never be forgotten that often the temperature continues to fall for some minutes, or even for hours, after removal from the bath. This is especially true in cases of acute pyrexia; under these circumstances serious results are said to have been produced by keeping patients in the bath too long, waiting for the temperature to reach the normal point.

Ziemssen modified the use of the tepid bath by gradually cooling it while the patient was in it by the addition of water at a low temperature. This is, of course, an efficient procedure, capable of producing any effect that can be obtained by the abstraction of heat. Caspari (*London Med. Record*, 1873, vol. i. p. 796) believes that in very feeble subjects the use of cold baths should be superseded by the method of Ziemssen. He places such patients in a hip-bath at a temperature of 80° F., and, whilst the upper part of the body is vigorously rubbed, pours over it water at 60° until the temperature of the bath is lowered to 62°, occupying about fifteen minutes in the procedure. On the other hand, Glénard calls attention to the fact that the long gradual bath is much more wearying and exhausting to the patient than the short decisive plunge, and affirms that in his experience it is no less disagreeable to the sick man. Further, the clinical results achieved by Liebermeister, Glénard, and others prove that adynamia, except of the gravest kind, is not a contra-indication to the use of the cold bath: so that it seems to me that the choice between the cold plunge and the gradual cooling is to be determined by the exigencies and circumstances of the individual cases; either may be employed with the one result, provided it is always carefully seen to that the measures used are severe enough, and are put into application with sufficient frequency to keep the axillary temperature below 102½° F.

The exact manner in which Brandt's method should be employed is briefly but sufficiently summarized in the following instructions to the nurses at the Croix

Rousse Hospital, Lyons. They represent the exact plan employed by Glénard, who, it will be remembered, contends that no typhoid-fever case will die if treated in this way from the beginning.

"The nurse will every three hours take the rectal temperature of the patient, and give him a bath at 20° C., of fifteen minutes' duration, night and day, until the thermometer placed in the rectum for five minutes does not register 38.5° C. The patient is taken to the bath, his night-dress removed, and he is plunged *up to the neck* in the water at 20° C., while the head is sprayed at 6°-8°, especially where there are cerebral symptoms. After the nervous symptoms have abated, the spray may be given at the same temperature as the bath. The affusion having lasted one or two minutes, the nurse rubs the limbs of the patient for three or four minutes; then he is left at rest. His breathing may become difficult, and his teeth may chatter, but he must remain in the bath for fifteen minutes. When he is about to be removed from the bath, the affusion is to be repeated. He should be kept at least fifteen minutes in the bath, even should the shivering set in from the commencement; and longer, should the shivering be late of appearing. He is then removed, his night-dress put on without drying him; a sheet is thrown over his feet; his mattress should be hard enough not to yield to the weight of his body, which should be covered by a sheet in summer (also by a light linen cover in winter). A little weak tepid soup is now administered, along with a mouthful of old wine, and he is left alone to rally from his shivering, which lasts fifteen to twenty minutes, sometimes for even an hour. Fluid nourishment should be given regularly, and always tepid. If the patient is very weak, a spoonful of old wine may be administered before the bath."

Cold affusions were practised very largely by Currie in various pyrexia, with undoubtedly most beneficial effect. He used water at from 40° to 50° F.; from a bucketful to four or five gallons being poured over the naked patient as he sat in a bath-tub. This affusion was repeated as often as was necessary to keep down the bodily heat. Currie supposed that the chief good was owing to the shock of the cold dash, and others also have claimed that the douche exercises some obscure reflex influence upon the nervous system. This is possible; but it does not appear to have been proven that the shock of the cold dash is greater than that of the cold plunge, or, indeed, that in either case the shock is other than deleterious in fevers. As an anti-pyretic measure, the simple cold affusion seems to me to be more troublesome and more terrifying than cold bathing, and, according to the researches of Liebermeister, it is much less powerful.

In order to avoid the labor to the nurse and the uneasiness to the patient which are involved in the use of cold water, various contrivances have been suggested for the refrigeration of those suffering from fever. Wet compresses or large bags filled with ice are often employed in Germany as adjuvants to more energetic measures, in order to lessen the number of baths re-

quired. They should be kept constantly applied unless the thermometrical record indicate otherwise.

It has also been proposed to encircle the patient with india-rubber tubing through which cold water is kept circulating.

Leube (*Deutsches Archiv für Klin. Med.*, 1871) claims that he has obtained the best effects from the use of ice mattresses. The details of his method are as follows:

"Two parallelogrammatic water-tight bags of india-rubber cloth, the one measuring unfilled twenty-eight inches long and eighteen inches broad, the other twenty-four inches long and eighteen inches broad, are to be filled with a freezing-mixture, composed of ice and salt. In order to allow comfort to the patient, the ice should be reduced to a powder and passed through a sieve. After five or six pounds of this ice-powder have been put into each bag, one to one and a half pounds of salt are to be thrown into each, and the orifice closed. Two bandages are then laid transversely across the bed, and the ice-bags are placed on them in such a way that the shorter corresponds to the trunk, the longer to the legs of the patient, who is to be laid upon the ice-bags after they have been covered with a gum blanket and a linen sheet. By means of the bandages the man is then tied down, one band passing over him above the knees, the other above the navel, and covered over with bed-clothes. The patients are said rarely to complain of the cold, and may be allowed to remain upon the ice mattress from an hour to an hour and a half."

If this plan is really efficacious in reducing the temperature, it offers such obvious advantages over cold bathing that it must eventually largely supersede the latter.

H. C. W.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, JANUARY 15, 1875.

THE PRESIDENT, DR. WILLIAM PEPPER, in the chair.

I. PERITONEAL tuberculosis.

II. Contracted kidneys and hypertrophied heart.

III. Cirrhotic liver and congested stomach.

DR. F. P. HENRY presented the specimens, and read the following histories:

"I. J. H., æt. 40, was admitted to the male medical ward of the Episcopal Hospital about August 1, 1874, for diarrhœa, and, after remaining for six or seven weeks, was discharged apparently cured. He was again admitted about three weeks ago, the diarrhœa having returned, and was first seen by me at that time.

"His symptoms on admission were—extreme emaciation, great feebleness, and profuse diarrhœa, averaging from twelve to fifteen watery stools in the twenty-four hours. There was no complaint of pain, and no cough. The abdomen was retracted, and slightly tender on pressure.

"A variety of remedies were used, without effect, to check the diarrhœa, which, before death, became an almost continuous watery discharge.

"The *autopsy* was made by Dr. Merrill, the resident physician, eighteen hours after death.

"The *right lung* was found to contain a number of miliary tubercles unevenly disseminated through its tissue, but could hardly be said to be *infiltrated* with these bodies. There was a cavity about the size of an egg at the apex, very superficially seated in the lung-tissue.

"The *left lung* was hepatized in the upper half of the superior lobe; a portion cut off sank in water. Tubercles were also found in small quantity in this consolidated portion and throughout the remainder of the lung.

"The *heart* was healthy.

"The *intestines* were covered with tubercles from the duodenum to a short distance below the ileo-cæcal valve.

"The *mesentery* also contained these bodies and numerous enlarged glands.

"A flattened tumor, several inches in circumference (about six), was found in the mesentery at or near its junction with the vertebræ. It is supposed to consist of a mass of tubercular mesenteric glands.

"The *mucous membrane of the intestine* was pale, but apparently healthy; there was no appearance of tubercle or ulceration in it.

"The *stomach, liver, kidneys, and spleen* were healthy.

"The urine was examined before death, and found free from albumen.

"I would like to ask the opinion of the Society as to the cause of diarrhœa in this and similar cases.

"In *this* case, it has occurred to me that the tumor found in the mesentery might have caused pressure sufficient to paralyze some of the sympathetic fibres supplying the small intestine, and thus have given rise to a state of congestion which relieved itself by a transudation of serum.

"If nerve-fibres should be found to be involved in this mass, support would be given to this theory.

"No traces of inflammation were found in the peritoneum.

"II. The specimens of *contracted kidneys and hypertrophied heart* were taken from a girl æt. 17, who was admitted to the Episcopal Hospital on the 7th of December.

"She presented the typical symptoms of chlorosis,—a greenish-yellow skin, pearly conjunctivæ, amenorrhœa, and a marked continuous musical murmur heard on applying the stethoscope over the course of the internal jugular vein. There was also a blowing murmur with the first sound of the heart, heard most distinctly at the apex.

"Under the use of iron and quinia the girl steadily improved up to December 16. At this time she became more feeble, lost her appetite, and complained of colicky pains in the abdomen. Her condition remained about the same until the evening of December 18, when she became partially comatose, and died at midnight.

"At the *autopsy*, ten hours after death, the *left ventricle* of the heart was found hypertrophied, and the *kidneys* contracted.

"The *lungs* were perfectly healthy, as were also all the abdominal organs except the kidneys.

"The cortical portion of the kidneys is atrophied, and the kidneys are quite small; but it must be borne in mind that the patient furnishing these specimens was a remarkably small individual, not five feet in height, and weighing, I should say, under one hundred pounds when in an ordinary state of health, so that the small size of the kidneys may be more apparent than real.

"This is believed to be a case of simple hypertrophy of the heart caused by contracted kidneys.

"III. The third set of specimens was removed from a woman æt. 53, who was admitted to the hospital on December 8, 1874. She first noticed a fullness of the abdomen in July last, which increased for three or four weeks and then disappeared under medical treatment.

Early in October the abdomen began to enlarge again, and continued to do so until she applied for admission.

"At that time there were all the signs of abdominal dropsy, which existed in so great a degree as to cause orthopnœa for the first two or three days after admission. There was also well-marked jaundice, and some œdema of the legs and feet. The abdominal distention was so great that the liver could not be felt, and this distention rendered it also impossible to determine accurately the vertical diameter of the liver. The bowels were moved three or four times daily without medicine.

"There was no albumen in the urine. As the patient refused to submit to tapping, elaterium in daily doses of one-tenth grain was given, but produced no increased action of the bowels; on the contrary, the bowels became rather more constipated.

"On the 18th, the skin on the back and legs ruptured; this was followed by a steady discharge of serum. The abdomen became softer, but the constipation became more obstinate, and about this date she was given one-tenth grain of elaterium hypodermically; this produced no effect, and was repeated on the 20th. The elaterium again produced no effect. On the 22d, there was slight discharge of fæces in response to an enema.

"The patient became gradually weaker, the jaundice more intense, and a mild, cheerful delirium supervened.

"For the last two days of her life she swallowed with difficulty, and was supported almost entirely by nutritive enemata.

"At the *autopsy*, six hours after death, the *abdomen* was found distended with yellowish serum; the *liver* hard, covered with nodules, and of a brownish-yellow color; weight, three and a half pounds.

"*Spleen* much enlarged and congested, its capsule thickened and opaque, but easily detached.

"*Kidneys* healthy; *heart* also healthy.

"Commencement of *aorta* atheromatous.

"*Lungs* hypostatically congested, otherwise healthy.

"The *stomach* contained a quantity of coagulated blood, which must have been poured out shortly before death, as no hæmatemesis had taken place. Mucous membrane of stomach reddened and swollen."

Dr. WHARTON SINKLER said that the patient from whom the first specimens were derived had been under his care during almost the whole of his term of service, which had immediately preceded that of Dr. Henry. His illness began with an attack of poisoning, apparently by the rhus toxicodendron, and he stated that he had been in perfect health up to that time. Immediately after this, diarrhœa came on.

When admitted to the hospital, about four weeks later, his arms, hands, and face were covered with eczema, and there was a profuse and obstinate diarrhœa. The diarrhœa was finally checked, and there were no lung-symptoms; but during convalescence there appeared to be some loss of power in the lower extremities, and, if Dr. S. remembered rightly, some disordered sensation.

He desired to know whether the spinal cord had been examined, and whether there remained any traces of the skin-affection.

Dr. HENRY replied that the cord had not been examined, and said that while the patient was under his observation there was no loss of power in the limbs except such as could be attributed to wasting and weakness.

Epithelial cancer of rectum.

Dr. LEONARDO S. CLARK presented the specimen, for Dr. ABRAHAM S. GERHARD. Mrs. Christine S., æt. 52 years; a widow for four years; housekeeper; native of Würtemberg, Germany; had borne four children; no miscarriages; no previous disease of consequence; past the climacteric six years; no carcinoma in family from grandparents down, so far as known; suffered

from lateral curvature of the spine (to the right) from childhood, the cause of which is not known; she has children aged respectively thirty-two, thirty, twenty-four, and sixteen years, all healthy; husband died of general carcinomatous degeneration of lungs, pancreas, and mesenteric glands.

Mrs. S. was of phlegmatic temperament, had blue eyes, light-brown hair, and a gentle disposition. The peculiar cachectic appearance was well marked.

Nine years ago she first noticed a lancinating pain in the rectum. She never mentioned it for a period of nearly seven years, although she suffered greatly at times. Two years ago she complained to one of her daughters that "her womb was forced down." The fact was communicated to her physician, but, on account of her great diffidence, no personal examination was made until about one year ago, when it was found, upon both vaginal and rectal examination, that the womb was retroverted and prolapsed, and that this displacement of the organ was caused by a large tumor of the rectum above it, which tumor was to the touch hard, nodulated, and cartilaginous. *Cancer of the rectum* was immediately suspected, and the diagnosis was subsequently confirmed by Drs. Goodman and Merklein.

The symptoms from that time until death were those of sharp, lancinating pain through the pelvis, great difficulty in defecation, accompanied with excessive tormina and tenesmus, partial protrusion of the uterus and posterior portion of bladder, with general failing of strength. On New-Year's day she paid a visit to her physician, although in great pain and distress, and on the morning of the 2d of January she died with symptoms of obstruction of the bowels, although there was no stercoraceous vomiting.

The *post-mortem* examination was made by Dr. L. S. Clark, twelve hours after death.

Rigor mortis was well marked; the body was emaciated, and the belly enormously distended with gas; its integument was partially decomposed.

Upon dissection, the peritoneum was found to be universally injected, and there were a few pelvic adhesions. The small and large intestines were greatly distended with gas and fecal matter, which had to be evacuated before the pelvic organs could be removed.

Upon removal of the latter, the uterus and bladder protruding through the vulva, a hard, cartilaginous, nodulated mass was found occupying the rectal walls for a distance of about six inches in length and two and a half inches or more in diameter, starting from within three inches above the sphincter ani. To this was adherent a portion of the small intestine. All the other pelvic and abdominal organs appeared to be normal, except that there was some erosion of the os uteri.

A longitudinal section of the diseased part showed the canal to be pervious, the mucous membrane near the centre of the diseased mass to be ulcerated and of a dark congested appearance. The knife, in passing through the morbid tissue, grated, and the part felt dense. The cut surface was white and streaked.

The PRESIDENT inquired of the surgeons present whether the submucous form of cancer of the rectum, of which this appeared to be an example, was more frequent in their experience than that attended by out-growths from the mucous membrane encroaching upon the lumen of the canal. His own experience furnished more of the latter variety than of the former.

Dr. JOHN ASHHURST, JR., said that no doubt, in the majority of cases, the growths ultimately involved the mucous membrane and projected into the bowel, but in the early stages the mucous membrane might not be involved. In the case just reported, he thought that the fatal result was due not so much to the existence of cancer as to the presence of some independent source

of obstruction (such as a volvulus), as shown by the fact that after death the bowel was found pervious. Probably had this patient lived longer, and the disease thus been allowed to run its course, the mucous membrane would have become implicated, and the growth would have protruded into the gut, perhaps itself eventually producing fatal obstruction.

Dr. R. M. BERTOLET was inclined to agree with Dr. Pepper that cancer of the rectum most frequently manifested itself in a protrusion of the mucous membrane towards the lumen of the tube. Indeed, Billroth has pointed out that the rectum is the favorite seat of that form of epithelial growth known as adenoma, which, beginning as a hypertrophy of the follicles of the mucous membrane, involves the outer portions of the bowel secondarily.

The PRESIDENT said he had been impressed with the difference in the appearances produced by cancerous infiltration of the submucous tissue in different parts of the alimentary tract. Thus, at the pyloric orifice the disease very often goes on to extreme obstruction without ulceration, and especially without formation of growths projecting from the mucous surface. In cases of cancer of the rectum, even in its early stages, on the other hand, it had seemed that there was much more frequently, in addition to submucous thickening, more or less of such free growth.

Dr. PEPPER desired also to know whether it did not coincide with the experience of the members where death has ensued during organic disease of the bowel to find at the autopsy a greater degree of apparent perviousness than was anticipated before death, when, indeed, the bowel might seem to be almost completely obstructed.

Dr. ASHHURST said that the remarks of the President were no doubt correct. As he (Dr. A.) had already remarked, he did not doubt that in this instance the fatal obstruction was due to a twisting of the bowel or to some similar cause, and that the patient therefore actually died from intestinal obstruction, and not from cancer.

The specimen was referred to the Committee on Morbid Growths, which reported, February 11, 1875, as follows:

"The rectal tumor presented by Dr. Clark is an epithelial carcinoma.

"The peripheral portions of the growth show not only a regular cylindrical arrangement of the epithelial elements, but also a distinct limiting membrane or tunica propria. In the more central portions of the tumor the arrangement is less suggestive of a glandular structure; the tunica is absent, and the connective-tissue stroma is more richly developed, but not to such an extent as to warrant the designation of scirrhus."

(To be continued.)

GLEANINGS FROM OUR EXCHANGES.

TREATMENT OF TRAUMATIC ANEURISM (*The Lancet*, December 12, 1874).—Mr. Bryant gives three cases of aneurisms which were the results of wounds of healthy vessels, and were situated on parts easily accessible. In these respects they differ greatly from aneurisms due to disease or degeneration of the arterial walls, and from aneurisms deeply situated or springing from the great vessels in or near the trunk. For these the treatment by incision has not received the sanction or approval of the majority of English surgeons. But for those following wounds, treatment by incision into the sac, and the application of a ligature or of torsion to both ends of the artery, is constantly practised, and has been

attended by marked success. This difference is easily accounted for. In traumatic aneurisms the artery is, in the majority of instances, otherwise healthy, is readily closed, and speedily repairs; but the case is different where the aneurism springs from a diseased vessel, for then the condition of the artery will not usually permit the application of a ligature or of torsion, or the vessel will not take on proper reparative action, so that secondary hemorrhage is liable to occur in a shorter or a longer time.

The chief difficulty in treating an aneurism by incision and by closing both ends of the divided vessel is, of course, the severity of the hemorrhage during the operation. But this difficulty may, as a rule, be easily overcome by pressure on the main trunk, or by pressure on the open mouths of the vessels in the sac. In cases of more than ordinary difficulty, the Esmarch bandage may be applied with great advantage where the aneurism is situated in the extremities. By this means the limb may be thoroughly exsanguinated, and the operation rendered as facile as in the cadaver.

NÉLATON'S METHOD IN CHLOROFORM-NARCOSIS (*The American Practitioner*, February, 1875).—Dr. M. H. Jordan reports the case of a girl, æt. 18, to whom chloroform was administered preparatory to the extraction of a tooth. After four or five inhalations, some spasmodic movements were observed, the pulse became excessively small and feeble, and, together with the respiration, soon ceased to be perceptible. The entire muscular system was completely relaxed, and the lips, face, and hands grew livid. The patient's body was immediately inverted, the jaws were pried open, and efforts at artificial respiration were made by alternately pressing in the thorax and abdomen. After about five minutes had elapsed, there was a feeble attempt at respiration, followed after a long interval by others, and a gradual return of the pulse, until it was deemed safe to place her on a bed. As soon as she was put in the horizontal position, however, the breathing again ceased and the pulse disappeared. She was again instantly placed with her head downwards, and artificial respiration was renewed. After a prolonged interval, the breathing was re-established, and the pulse again returned. There was no further trouble, except an inclination to stupor, which was counteracted by stimulating applications to the spine, and hot foot-baths.

NEURALGIA OF THE LARYNX (*The Medical Press and Circular*, January 20, 1875).—Dr. Clinton Wagner has found that neuralgia of the larynx is occasionally met with as a true neurosis, and independent of any other morbid process in the same individual.

The pain, which is at times intense and agonizing in its character, is felt along the thyroid cartilage and anterior part of the neck, the nerves implicated being the superior and inferior laryngeal, especially the former.

There is also at times a feeling of oppression or choking; the voice is weakened, and the pain increased when the least exertion of it is made.

The treatment he has found most successful has been large doses of tinct. iron and quinine, and insufflations of tannic acid and morphia into the larynx. Aconite liniment over the seat of pain gives temporary relief. Counter-irritation from blisters or tinct. iodine have been recommended. Hypodermic injections of morphia are also useful. Electricity in the form of the faradic current, in the few cases he has employed it, has had the effect of increasing the pain from the muscular excitation it produces, and the constant current in his hands has failed to give the relief claimed for it by others who have used it.

BLEEDING FUNGUS GROWTH FROM THE URETHRA (*The Lancet*, December 12, 1874).—Mr. Hutchinson

reports the following case: A woman, aged thirty-three, had suffered for five or six years from a bleeding growth of the urethra. The bleeding first came on about five years ago, after severe muscular exertion. The patient had been in several hospitals, without gaining any permanent relief. Four years ago the growth was removed by the knife and the cautery, but returned. Since then she has been subject to severe hemorrhages from the part. The actual cautery was recently applied, with some relief from the bleedings for a few days.

The interest of this case lies in the fact that there is a family history of the hemorrhagic diathesis, and also of recurrent (malignant?) growths. The mother's sister had a "bleeding cancer of the lip," which was removed, but re-formed on the tongue. One sister is subject to severe epistaxis, and the patient's son has been affected with epistaxis for three years. Another child died at the age of six years with bleeding from the nose and mouth. A sister of the patient has severe floodings after parturition, and has also a large red tumor of the left upper eyelid, which has been removed twice.

MISCELLANY.

GARIBALDI AS A SANITARY REFORMER.—Few meetings of modern times have been more interesting than that of King Victor Emanuel and General Garibaldi. It was a fitting epilogue to the glorious drama of Italian unity. But the subject of their conversation was not less noteworthy. It was the sanitary improvement of Rome by the cultivation of the Campagna and the embankment of the Tiber. This is an old project of Garibaldi's, which he has kept in the background till the flag of united Italy floated from the Capitol. The cry of "Roma o morte!" he has now exchanged for that of "Roma e vita!" and with characteristic foresight and fervor he has seen and determined the two points to be attacked, and the king listened to them and promised his hearty co-operation. For effecting this sanitary revolution Garibaldi proposes the employment of relays of the Italian army and of the laboring classes of the Roman province in the prosecution of the works on the Campagna and the Tiber; and the idea, fairly considered, is by no means a Utopian one. Who but the legionaries under the old republic constructed the roads and the walls whose convenience and strength have been the admiration of modern times? And what better occupation could be found for Italy's overgrown army than the employment of detachments of it in breaking up the waste land of the Agro Romano and preparing it for its old agricultural uses? The embankment of the Tiber and the regulation of its course is a similar task not less appropriate for the *cives Romani* of these days, whose aspiration it should be to make Rome the centre of more masculine interests than those of the *dilettante* and migratory foreigner. Money—the weak point of all Italian undertakings—must, of course, be provided; and abler financiers than the present purse-bearers of Italy must arise before the sanitary improvement of Rome can be satisfactorily begun.—*London Lancet*.

A CORRESPONDENT writes to us as follows: "Why is it that medical schools are so far behind the times? Why are medical degrees given away so freely? The value of a thing is generally estimated by the time and labor required to obtain it: if this be the case, an M.D. is not worth as much and is not so respectable as a horse-doctor's degree (D.V.S.). To obtain the former, one has to spend a year at a medical school and make the faculty believe that he has opened a medical book once in a while during the last three years; to get the latter, one has to study six years at a good school. Still we think ourselves better than horse-doctors. The medical schools think too much of patronage. It seems as if their object is rather to make money than to increase the value of the degree. A degree of M.D. should be made as honorable as that of Ph.D. or of Sc.D. Why should not students be obliged to pass a preliminary examination?"—*Boston Medical and Surgical Journal*.

A LEDGER and set of day-books for the use of physicians has just been published by Mr. U. L. Hitchcock, of New York, on a new and very simple plan. The day-book is in twelve sections, one for each month, each one so small as to be easily carried as an ordinary pocket-book. The account of each patient is kept on two horizontal lines, one for charges and the other for credits. The totals for the month, which can be seen almost at a glance, are to be transferred monthly to a ledger of four hundred pages, in which each patient's account is extended on two lines, similar to those of the day-book, to the end of the year. The work of posting is thus rendered exceedingly simple and rapid.

WE desire to call attention to the "Case Record Book." There are two books, one for the office and the other for the pocket. The latter is really a visiting-list, formula-writer, prescription-blanks, and a tag upon which a copy of the prescription given, and any notes of the case, may be recorded. To all in large practice these books must prove a great convenience.

THE motto over the main entrance to the hospital at Vienna is "Saluti et solatio ægrorum," and that over the Anatomical and Pathological Institute is "Indican- dis sedibus et causis morborum." On these two principles the science of medicine may truly be said to be built.—*London Lancet*.

FROM the Report of the Peking Hospital for 1873, by Dr. John Dudgeon, we learn that the aged, infirm, and debilitated generally are recommended by Chinese physicians to drink urine to restore health!—*Medical Times and Gazette*.

ACCORDING to the *Wiener Medizinische Presse* for January 3, the first dental school has just been announced in Vienna. The course of lectures and practice lasts six months, the school being open from 8 A.M. to 5 P.M.

AN ice-inspector has been appointed in London, whose duty is to examine and certify to the safety of the ice in the public parks.—*Boston Medical and Surgical Journal*.

NOTES AND QUERIES.

MEDICAL OFFICERS OF THE BRITISH NAVY.

THE following Order in Council has been issued:

"At the Court at Osborne House, Isle of Wight, the 4th day of February, 1875.

"Present—The Queen's Most Excellent Majesty in Council.

"Whereas, There was this day read at the Board a memorial from the Right Honorable the Lords Commissioners of the Admiralty, dated the 1st of February, 1875, in the words following:

"Whereas, We have had under our consideration the position of the Medical Officers of your Majesty's Navy; and, whereas, we are of opinion that it will be for the benefit of your Majesty's service that the following regulations shall be established, we beg to submit them most humbly for your Majesty's approval:

"1. That Surgeons on entry shall have the same relative rank as Paymasters, Chief Engineers, and Naval Instructors,—namely, shall rank with Lieutenants under eight years' seniority, and shall have uniform corresponding to such relative rank.

"2. That Staff-Surgeons shall be denominated "Fleet-Surgeons," and Staff-Surgeons second-class simply "Staff-Surgeons;" the distinction in rank between these two grades to be denoted by a small difference in the uniform.

"3. That Inspectors-General shall be compulsorily retired at the age of 60, on £2 per day, provided they shall have completed the period of service now required to entitle them to the *maximum* half-pay of their rank.

"4. That Deputy Inspectors-General shall be compulsorily retired at 60, if in the first six of their rank, at 33s. per day, others at 30s. per diem, provided that they shall have completed the period of service now required to entitle them to the *maximum* half-pay of their rank.

"5. That Fleet-Surgeons and Staff-Surgeons shall be placed on the same scale of retirement as Chaplains and Naval Instructors, Secretaries, and Paymasters; that is, the *maximum* to be £450 per year instead of £400.

"6. That any Fleet-Surgeon shall have the option of retiring after twenty years' full-pay service in all ranks at 15s. per day, and after twenty-five years' service at 21s., subject in each case to our approval; but that of those now on the list, not more than ten shall retire under this clause in each year (the officers having the option according to seniority), unless we should approve (with the consent of the Lords Commissioners of your Majesty's Treasury) of a larger number so retiring.

"7. That of the medical officers to be hereafter entered, all shall have the option of so retiring, subject to our approval in each case; and we beg leave to represent to your Majesty that the Lords Commissioners of your Majesty's Treasury have signified their concurrence in the proposed arrangements."

"Her Majesty having taken the said memorial into consideration was pleased, by and with the advice of Her Privy Council, to approve of what is therein proposed. And the Right Honorable the Lords Commissioners of the Admiralty are to give the necessary directions hereon accordingly.

"ARTHUR HELPS."

—*London Times*, February 6, 1875.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

THE next conversational meeting will be held at the hall of the College of Physicians, Wednesday, March 10, at 8 o'clock P.M.

Dr. James Tyson will read a paper; subject, "The Treatment of Bright's Disease of the Kidney."

The medical profession in the city are cordially invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM FEBRUARY 23, 1875, TO MARCH 1, 1875, INCLUSIVE.

SMITH, A. K. SURGEON.—Relieved from duty in the District of New Mexico, and assigned to duty at Fort Hays, Kansas. S. O. 21, Department of the Missouri, February 18, 1875.

WHITE, R. H., ASSISTANT-SURGEON.—Granted leave of absence for two months, with permission to apply for an extension of six months. S. O. 41, Military Division of the Atlantic, February 26, 1875.

YEOMANS, A. A., ASSISTANT-SURGEON.—At the expiration of his present leave of absence, to report in person to the commanding officer, Newport Barracks, Kentucky, for duty. S. O. 31, A. G. O., February 23, 1875.

ADAIR, G. W., ASSISTANT-SURGEON.—When relieved by Assistant-Surgeon Yeomans, to report in person to the Commanding General, Department of Texas, for assignment to duty. S. O. 31, c. s., A. G. O.

SATURDAY, MARCH 13, 1875.

ORIGINAL COMMUNICATIONS.

ON THE USE OF IODIDE OF POTASSIUM IN SYPHILIS.

BY JOSEPH R. BECK, M.D.,

Fort Wayne, Ind.

AT the meeting of the Indiana State Medical Society for 1874, I was appointed to read a paper on the iodide of potassium, in 1875.

This article will comprise extracts from the said paper only in so far as they are pertinent to the subject above stated, will be very practical, and make not the least pretension to scientific research. It has been hastily thrown together by reason of what I deem to be fallacious teaching, as found in a paper in the *American Journal of the Medical Sciences* for January, on "The Use of Mercury in the Late Stages of Syphilis," by Dr. Fred. R. Sturgis, of New York.

I decline any scientific controversy in the matter at present, because my data, although very numerous, are not yet sufficient "to establish the theory convincingly" by the only way in which this can be done,—namely, the production of overwhelming statistical statements. However, I am pleased to be able to give Dr. Sturgis (and other mercurialists) some food for contemplation in the two cases which I shall hereinafter instance, and hope that he will agree with me that these cases were in the highest degree desperate and typical ones, and will, after a perusal of them, give some credit to the "anti-mercurialists."

Of course, no one will expect all the points of argument to be covered in a paper of this description. I intend to make an exhaustive review of the matter at a future day, when I shall contribute a large number of the very worst cases of syphilis; but for the present this small paper must answer.

I do not now use, nor have I for a long time past made use of, mercurials in the treatment of syphilis. The fact is, I am entirely satisfied that in the treatment of any phase of syphilitic disease mercurials do harm. This sweeping denunciation of so ancient a remedy in this disease as mercury makes it well for me to state that I *do* use mercurials in *some* diseases, although *never* in syphilis.

But why do I not employ mercury in the treatment of syphilis, particularly since it has proved efficacious in the hands of so many in causing the symptoms of that disease to disappear very quickly indeed? Well, I reply, that very fact constitutes my reason. It *does* act quickly, entirely too rapidly to be in the least degree reliable, in my estimation. We are well aware of the fact that under the use of mercurials secondary manifestations may be rapidly dissipated, and we have been enabled, owing to this fact, to discharge our patients in a few weeks without spot or blemish. But, alas for this treatment! we have in *every* case only succeeded in *masking* the disease, and, after

another suitably long period of fermentation, we will surely have to deal with its tertiary manifestations. I use very emphatic language here, and words which it is impossible to mistake the purport of; but I close this item by the still stronger assertion, *that every case of secondary syphilis which has been successfully (?) treated by mercurials will, as surely as the sun rises, reappear as tertiary syphilis, if the patient lives long enough.* I feel warranted also in saying in this connection that many a case of mercurially-cured secondary syphilis passes from beneath our unskilful hands to the grave, labelled in the mortuary list as a victim to some intercurrent disease, when, if the facts could be known, the said intercurrent disease would show itself to be simply and truly an obscure invasion of tertiary syphilis. I have known such cases to occur in the practice of some of my medical friends. Syphilis, either secondary or tertiary, cannot be treated to a *permanent* cure in a few weeks or a few months. A radical, permanent cure requires fully a year of careful treatment, and often more; and I feel very well satisfied if I can dismiss a tertiary patient from treatment without a mark in eighteen months.

"Authorities" on the subject say that the iodide of potassium is the remedy *par excellence*, in the tertiary forms of the disease, but that it is not so good as mercury, or a combination of the two, in the secondary. Now, my readers, if I have told the truth heretofore, then all such statements as this last are unqualifiedly false. I refer you for proof of my assertion to your own mercurialized cases. Have you or not had the tertiary symptoms to treat after you had cured the secondary by the use of mercurials? You will, of course, reply in the affirmative. Then, did you ever see or hear of a case which in its secondary form had been treated to a cure by the iodide of potassium alone recur as tertiary? I presume that if your experience has been similar to mine (and I know of some cases which date cures back to 1860), your reply this time will be decidedly a negative one.

What does this demonstrate? Simply that the iodide of potassium *cures* syphilis, and that mercury only *masks its symptoms*. I have over and over again, in parties living in four different States, and in situations where sanitary surroundings exerted not the slightest general influence, seen the very worst cases of tertiary follow upon supposed mercurial cures of secondary syphilis.

I shall now draw these remarks to a conclusion; and, after again advising you against the use of mercury in *any* stage of syphilis, I pass at once to the relation of the history of two cases, selected from a large number, because they are, to a great extent, typical illustrations of the facts which I have just set forth.

Case I.—In November, 1871, I was invited by D. A., resident in this city, and, at the time, the patient of another practitioner of the same place, to visit him. I did so, and found him in a horrible condition. After a short conversation, he requested me to take charge of his case. To this request I acceded, stipulating only that he should at once discharge his former medical adviser, owing to the fact that, although a professed

regular, I would not consult with him. This he at once did, and I took the case, promising him at the time a perfect and permanent cure. He was at the time confined to bed, being very anæmic and exceedingly weak. He had been steadily mercurialized by his adviser during a period of nearly three years, and what tissual destruction the disease had not wrought was most ably supplemented by the ill-advised remedy. Almost the whole of the right buttock had been destroyed by ulceration, and the whole of the muscular portion of the left arm from the elbow to the axilla and acromion process, with a very slight exception, had disappeared in the same way. There existed three gummatus tumors on the skull, and this was the extent of the damage. A more unpromising case could not well be imagined, especially as the patient was a man of notoriously bad habits.

I treated him in the manner I shall hereafter relate, from November, 1871, until February 1, 1873, a period of fifteen months, and he is now almost as perfect physically as he was prior to the contraction of his disease. This case had its origin in what certain self so-called leaders in syphilography are pleased to denominate a "chancreoid." Excepting the annoyance attendant upon a very profuse pytalism, occasioned by the mercury yet remaining in the economy, the case began at once to improve, and, although the habits of the patient have not been such as I desired in every respect, yet the progress to a cure was very rapid, and pushed along without the least hindrance. *This was a perfect, not a speedy, cure.*

Case II.—On the 1st of August, 1874, A. K. R. came from middle Ohio, at the instance of a mutual friend, to consult me in reference to his case. It was one of tertiary syphilis, and its history began as far back as 1851. In the spring of that year he contracted a soft sore (some persons persist in calling them chancreoids), which, after steadily progressing for about three weeks, finally healed under treatment. In 1853 he was attacked by all the usual secondary symptoms of the disease, which, however, gave way in about two months under the exhibition of mercury, and his medical adviser pronounced him cured. In August, 1857, he experienced a return of the malady, but this time in its tertiary form; and from that time until I took charge of the case, covering a period of seventeen years, he was never for one moment free from the tortures incident to the disease.

When I examined him, after entirely stripping him, I found him totally bald, with eleven gummata on his skull, and numbers of such tumors on other parts of the body; indeed, there was not a superficial bone in his body but what presented more or less of these tumors in all stages. Even the scapulæ were so affected. Besides all this, the whole palmar surface of the left hand presented one open ulcer, and another large destructive ulceration was located on his right hip. In addition to all these *minor* matters, the patient *presented very apparent symptoms of commencing paralysis of the lower extremities, all signs of which disappeared early in the treatment.* He was always a man of good habits, but since the last invasion of the disease he has had such an excruciating head-pain all the time that he resorted to the use of opiates for relief, and became a confirmed opium-taker.

I promised this patient a *certain* though not a *speedy* cure. He has had my usual treatment for six months now, and is almost entirely well, but I shall continue to treat the case for another six months, in the manner hereinafter indicated, unless in the interval iodism is to

some extent induced, in which event he shall be *perfectly and permanently cured.*

In treating syphilis, after examination, I prescribe the following: Iodide of potassium, 7 drachms; ammonio-citrate of iron, 4 drachms; distilled water, 2 fluidounces; syrup of orange-peel, peppermint-water, of each 3 fluidounces. Make into a solution, and give a tablespoonful before each meal. Also, Fowler's solution of arsenic, 3 fluidrachms; simple syrup, orange-flower water, of each, 4 fluidounces. Make a solution, and give a teaspoonful after each meal. If some anæmia be present, which is frequently the case, especially if the patients have been mercurialized, I order, in addition to the above, Sulphate of quinia, 1 drachm; reduced iron (Quevenne's), 2 drachms; extract of gentian, sufficient. Make a mass, divide into sixty pills, and give one every three hours. Also, the following: Cod-liver oil, 7 fluidounces; fluid extract of valerian, 1 fluidounce. Shake the bottle, and give a tablespoonful every three hours. If, in addition to the ordinary constitutional disturbances, I have to deal with extensive ulcerations, I order hydrate of chloral, 1 ounce; distilled water, 2 fluidounces. Mix, and brush over the ulcerations thoroughly three or four times daily. If the ulcerations are situated upon dependent portions of the body, I support them by adhesive straps, which should be frequently changed. Any other symptoms which may require urgent attention should be met "*secundum artem.*"

Now, the foregoing constitute my *first* prescriptions only. In each of the succeeding prescriptions there should be added successively one drachm of the iodide of potassium to its formula, and half a drop to the *dose* of the Fowler's solution in the arsenical formula. The iodide should then be carried up drachm after drachm in strength with each successive prescription, until we reach twenty or twenty-five drachms' strength to the formula, *or as much more as is necessary*, taking care to order the increase made only with each succeeding fresh prescription. The strength of the arsenical solution is to be carried up *seriatim*, as stated, until a dose of five drops of the Fowler's solution is reached, at which point I hold the patient until slight symptoms of the constitutional poisonous action of the drug are developed. The arsenic is then finally omitted as an adjuvant. The iodide, however, I carry up, in ever-increasing quantity, until symptoms of decided iodism are induced, when its administration is ordered stopped for a week; then it is again commenced, and if the iodism again shortly ensues, I can most confidently discharge my patient, perfectly and permanently cured, with the poison of syphilis, and, let me add, that of mercury, forever eradicated from the system.

In order to test the truth of the latter assertion, I have been accustomed to test every patient, in about a year after all treatment had ceased, with ten-grain doses of the iodide of potassium; and the test has invariably produced profuse iodism before one drachm of the drug has been consumed in these small doses.

My experience with the iodide of sodium salt has been, if not entirely disastrous, at least entirely negative in results, and for this reason I do not use it.

I close this rapid and imperfect sketch of my subject by a short abstract of a paper defining the action of the iodide of potassium upon the blood. This abstract concerning the reactions of the iodide when administered medicinally is of a paper on that subject by Professor Kammerer, from *Virchow's Archives*, 1874, and "Memorabilien," xix. 4.

In the stomach the iodide either undergoes no change, the elements of the ordinary articles of food being incapable of decomposing it, or else, by means of the chlorine, hydriodic acid is formed, by which, however, the ultimate reactions are not modified. Entering the circulation in an exceedingly dilute state, the iodide is at once decomposed, by the superabundant carbonic acid, into free iodine and the carbonate of potassa. Now, the iodine will have the greatest affinity for those substances in the blood with which it makes the most complex combinations, this affinity being most intense at the moment of the iodine becoming free. Therefore, of these substances in the blood, those first acted upon would be the "miasmatic matters and ferments;" next to these the fibrinous, and then the albuminous substances; and last of all, the fats. The iodine acts upon these substances by virtue of its disposition to take the place of their component hydrogen. It, however, does not form permanent compounds with them, but, having broken up their chemical union, facilitates their oxidation in the oxygen of the blood. The free hydrogen combines with an equivalent of iodine, forming hydriodic acid, which is in turn attacked by the oxygen, iodine is again eliminated, and so the process is continued.

On the other hand, the other component of the iodide of potassium undergoes changes which supplement the action of the iodine. As the compound is decomposed, the potassa is changed into the hyperoxide of potassium, the only oxygen compound upon which the iodine does not act. Here we have, besides the iodine, a powerful decomposing agent, which, by its strong oxidizing effect upon organic substances, assists in the consumption of the blood-elements. The hyperoxide is reduced to potassium, which again combines with carbonic acid, and carbonate of potassa is produced as at first.

Hence the action of the iodide of potassium depends upon the decomposing effect of free iodine upon the substances contained in the blood, and their oxidation and consumption by the hyperoxide of potassium, a result, the writer observes, which is confirmed by clinical experience.

I have extracted this abstract from the *New York Medical Record* of October 1, 1874.

Finally, I firmly believe that in the iodide of potassium, used in the manner indicated above, we have a specific antidote to syphilis, either secondary or tertiary, and am sure that you will all be surprised at the rapid good effect produced by the drug in these large doses. Do not forget, however, that small and moderate doses are literally thrown away, and that only very large amounts are productive of permanent good.

TWELVE hundred and ninety-three volumes, most of them of European origin, were added to the library of the College of Physicians of Philadelphia last year.

A CASE OF PURPURA HÆMORRHAGICA REQUIRING TRANSFUSION.

BY J. M. BOISNOT, M.D.

DURING the night of June 4, 1874, I was called to see M. H., æt. 7 years; he had been for some time previous subject to troublesome epistaxis, etc. Both of the child's parents are in good health as well as circumstances, so that the child had had excellent hygienic care. There are four children, the patient being the third in the order of birth, and, with him excepted, all are in good health. There was at the time of my visit an intense general pallor, extending to the lips and internal surface of the eyelids, giving the patient a waxy appearance, and making more apparent the existing ecchymotic spots; these last were situated behind the ears, at the angle of the mouth, the roof of the mouth, and a large one, of six inches in diameter, over the region of the liver. Blood was noticed oozing from the nose, gums, and pharynx, while the quantity vomited led me to infer that there might also be internal bleeding. The pulse was feeble, quick and rapid; the respiration labored, the tongue pale, moist, and clean. The general expression of the face was anxious to a degree which might even call for the term frightened. The hemorrhage at this time was from the nose, and was sufficient to require applications for relief to both anterior and posterior nares.

As before stated, the history of the patient was that of a previously healthy boy, descended from healthy parents, in every way active and well. There being no obvious cause for the attack, I am disposed to attribute its origin to some interference with normal nerve-action, due to the shock from a fall from the second-story window upon the brick pavement years before, although no severe external injury could be perceived at the time. This may seem like going a great way in order to find a cause, but I am quite confident that I at one time removed the tibia for necrosis, which had its origin in fully as distant nervous shock, and from my experience in military surgery I think that the nervous shock accompanying and resulting from wounds and exposure eventuated in typhoid conditions, typhoid pneumonia, and phthisis many years after what was denominated complete recovery from the primitive conditions.

The treatment was, of course, first directed towards arresting the active epistaxis, by means of Monsel's salt applied to both the anterior and posterior nares by insufflation, which I employed successfully during the recent epidemic of smallpox in this city, in cases which I at first looked upon as requiring plugging of the nostrils by Bellocq's canula.

Internally, the administration of potass. chlorat., in combination with tr. ferri chloridi, was persisted in, while every attention was given to providing the most concentrated food. Rest was enjoined, with proper regulation of carriage-riding in the Park during the cool of morning and evening, so as to give as much pure air with as little excessive heat as was possible.

There could be noticed scarcely any improvement, and there were frequent returns of epistaxis, while the persistence of the ecchymotic spots was remarkable. The application of alcohol with brisk rubbing was maintained daily to the spine, and quinine, iron, and strychnia, together with stimuli in food-combinations, were freely administered. During the second week, at the suggestion of Dr. Keichline, of this city, the ol. terebinth., gtt. x-xv ter die, was given in sweetened ice-water. At the beginning of the third week there was improvement to the extent of an interval of four days without epistaxis, and, as the weather was oppressively hot, the patient was sent to Atlantic City. He stood the journey well, but in the night bleeding

recurred to the extent of alarming prostration; local and constitutional remedies were applied, and, on account of the stomach refusing food from the amount of blood swallowed, he was stimulated as much as he would bear. In the afternoon he was brought back to the city. The bleeding having been so excessive, and the consequent prostration so marked, I told the family, after a consultation with Dr. W. W. Turner, that the child could not live except transfusion was practised. I was the more fully impressed with this as a necessity from having been invited by my friend Dr. T. G. Morton to witness the procedure in a similar case in his practice, a full report of which he gave in the *American Journal of the Medical Sciences*, July, No. 135, pp. 116, 117. I feel quite confident that nothing else could have saved life in either case.

The condition of the patient on Monday, June 22, 1874, was critical in the extreme: pulse 160, feeble; surface cool, respiration panting; general lassitude, with disposition to drowsiness, amounting nearly to stupor. Transfusion of $\text{f}\text{3iv}$ of blood from the father yielded a result beyond our most sanguine expectations; in short, recovery began from that day, progressed, and at this writing, Nov. 2, is established. It is proper to state that on the third day following the transfusion, violent epistaxis recurred. This was arrested by plugging the nares, with the aid of Bellocq's canula. There was no internal medication, excepting quinae sulph., gr. iv daily, and the following, at the suggestion of my friend Dr. A. Frické:

R Tinct. nucis vomicæ, $\text{f}\text{3ss}$;
Acid. phosphor. dilut., $\text{f}\text{3ii}$;
Aque destillat., $\text{f}\text{3i}$;
Syr., $\text{f}\text{3ii}$.—M.

S.—Teaspoonful ter die.

The diet maintained was of the most concentrated character, such as juices of meats, eggs, milk, and cream, with a liberal supply of champagne daily.

Without entering into the consideration of the minute physiological conditions of the blood, and the agencies which affect it, I take it for granted that the blood is the medium that perpetuates both molecular and general growth, and through which repair is instituted. From what little I have seen of transfusion and its effects, I see no reason to oppose the views made public more than two hundred years ago, but rather to endorse the quaint words, "the blood may, if it takes, be of mighty use to man's health, for the amending of bad blood by borrowing from a better body." If the loss of blood causes a depression or a lowering of the vital forces, an extra supply should certainly be invigorating.

Respecting the method of transfusion, a rule applies to this as to all other operations in surgery, viz., the simplest is always the best. Undue haste in any part of the procedure must be avoided, and all preparations should be carried on away from the parties concerned: it is well to make every provision for what may occur in the way of accidents, rather than wish for things not at hand when, perhaps, too late. Hot and cold water, ice, old muslin, sponge, spirit of ammonia, stimulants, an operating or a pocket-case of instruments, in addition to those directly required in the transfusion, with at least two competent assistants, may be placed upon the list as requisites. The syringe should be in perfect order, for this is the instrument in this operation, and I certainly would not advise any one to run the

risk of being equal to the emergency and try to manufacture a syringe for the occasion from any glass one he may find about the house, for only a good blower could succeed in this.

The apparatus used for receiving and defibrinating (it should be termed "oxygenizing") the blood may be described as follows. It is not intended to be referred to as possessing any special merit over and above those already presented. There is scarcely any surgical apparatus which may not be extemporized, and *successfully*, when occasion requires and ingenuity suggests, but it is often a point to be able to connect luxuries and necessities. The receiver should be of a shape easily adapted to receiving the blood direct from the donor, and, being graduated, measures accurately the blood drawn, doing away with the necessity of transferring from one vessel to another, and serving as well for extra venesection should the quantity fall short of that deemed requisite. It can be readily and cheaply made, and, as I believe the air-tight syringe to be the best instrument for transfusion, the receiver should nicely fit the nozzle, and allow all the blood to be drawn into it. The application of all these means is the most apparent in that this operation is, in one respect, similar to that of tracheotomy for croup,—it is a last resort, allowed when there is little or no hope of anything else succeeding as life-saving. Therefore it is that all apparatus and all procedures should be as efficient as possible, and have economy of time as a principal feature.

I think it would have been simply impossible to employ the direct method in the case of this child, for even an ordinary amount of quiet could scarcely be obtained, and the use of an anæsthetic was not to be thought of. Proper care being exercised in the use of the syringe will give greater prospects of successfully transfusing blood free from any air whatever than by any other means that I know of. There are some conditions of the patient at the time of this operation, connected with it not dependent upon it, which it is well for all to know. The breathing becomes quite irregular, the efforts amounting to quite a struggle; the surface becomes cool and pallid, followed by rigor of unusual severity; the pulse is feeble and quite irregular, and fluttering. The patient repeatedly asks for water, and ice is taken with avidity even during the rigor; all the conditions are those generally accompanying a severe nervous shock. The treatment at this stage embodies the usual applications for restoration,—artificial heat, rubefacients, plenty of air, fanning, ammonia, stimulants, etc.,—and *must positively be persevered in until full reaction is established*. These symptoms seem somewhat alarming to one performing the operation for the first time, and might lead to the supposition that air had entered. I think they can all be explained by the fact of the heart being called upon suddenly to accommodate its action to a considerable quantity of blood after having been greatly depleted. Again, the shock may be greatly aggravated if the blood is introduced at too high a temperature; 100° is sufficient, or one or two degrees above may be allowed, to compensate for cooling in the handling. This last will be but

slight if the syringe is (as it should be) immersed in the same water which is used for heating the blood.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF R. J. LEVIS, M.D.

Reported by Dr. JOHN B. ROBERTS.

ENORMOUS HYDROCELE OF THE NECK IN A CHILD—PARACENTESIS OF THE CYSTS, AND REMOVAL OF THE SOLID PORTION BY THE ÉCRASEUR.

A FEW days after this child, now about three years of age, was born, there was observed a slight lump on the side of the neck, which has gradually increased in volume until it is at this time of the size of the child's head. The tumor extends from the ear to the clavicle, and from the chin outwards, hanging over the shoulder. It shows no signs of inflammation, is soft to the touch, and at various points presents fluctuation upon palpation. Some months ago it was tapped, and a considerable amount of fluid drawn off, after which, the parents state, a seton was introduced; but the treatment was not permanently successful, and the tumor has continued to increase in size.

The diagnosis of cystic tumor is easily made in this case, from the general characteristics of the swelling, and from the fact that there was serous fluid drawn off when the tumor was punctured.

To these cysts of the neck the terms hydrocele and hygroma have been applied, but they do not differ in nature from the serous cysts found in other parts of the body. They are more commonly situated in the glandular tissues, such as the ovary and mamma, and associated with adenoid tumors in the cervical region; but in this instance the cyst is developed in the cellular tissue of the neck.

They may be, and perhaps generally are, congenital, and contain serum, or serum mixed with blood; sometimes, however, the contents are thick and viscid, and occasionally solid matters have been found within them. In this case the cyst is multilocular, as can be determined by the lobulated appearance of the surface, and by the fact that fluctuation is felt in sections only, and not in continuity through the different diameters of the tumor.

The radical treatment of these cases of large hydrocele of the neck is difficult, for excision is frequently impossible, since prolongations of the cyst extend deeply among the important cervical structures, surrounding the vessels and nerves in such a manner as to render extirpation of the tumor absolutely impracticable; and, on the other hand, the injection of solutions into such large sacs, to induce obliterative inflammation, is attended with danger on account of the resulting constitutional disturbance.

In this case the tumor is so large that it would not be safe to attempt to dissect it out, for it undoubtedly has deep attachments and is intimately blended with the subjacent structures. Neither would it be advisable to lay open the sac and allow it to suppurate, nor, on the other hand, to inject into it tincture of iodine or

carbolic acid, for there would be an enormous surface which might perhaps absorb the pus or the medicinal agent and thus cause the supervention of toxic symptoms.

When the child first came for treatment, there was debility and a general want of tone which demanded the use of tonic remedies before anything operative was undertaken. Now the various cysts shall be punctured, and the contents evacuated by thrusting a bistoury into the tumor at three points, from which the serum is seen to escape; there is also much solid matter and material of gelatinous consistence, forming a portion of the tumor.

In order to have as small a suppurating surface as possible, a portion of the cyst shall be removed by the écraseur. Since, however, the tumor is not lobular or pedunculated, it will be necessary to devise a means to keep the chain around its base: hence these long acupuncture needles are passed through the mass, transfixing it in various directions, and then the chain is placed behind these needles and drawn tightly so as to constrict the portion to be removed. By drawing on the chain, this portion, which is collapsed to the size of an orange, is gradually crushed off from the underlying structures, without the hemorrhage which would certainly occur if the knife were used. The great force applied has, however, broken the chain of the écraseur when the parts are almost separated, and the operation shall be concluded by using the knife, since there will not be much hemorrhage now after the constriction which has been exerted before the chain separated.

The object in removing this portion of the cyst is to obtain a small surface for the occurrence of suppuration, and thus to lessen the danger of excessive constitutional disturbance. The wound is dressed with carbolic oil, and the little patient given a dose of chloral and morphia to allay pain and induce sleep.

[Four days after the operation, a colliquative diarrhoea, to which the patient had been liable, occurred, which could not be controlled, and the child died from exhaustion, while the appearance of the wound was quite favorable.]

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

SERVICE OF DR. LOUIS A. DUHRING.

Reported by ARTHUR VAN HARLINGEN, M.D.

EPITHELIOMA OF THE NOSE.

THE patient before us, a young woman some twenty-eight years of age, has suffered from this disease four years. It involves, as you see, the structures constituting the right ala of the nose, extending about halfway up towards the root; much destruction of tissue has taken place. The appearance presented is that of an unhealthy ulcer, covered with the products of suppuration and bordered by a rim of thickened and diseased tissue. The operation we shall employ for the cure of this case is as follows. Having provided ourselves with an abundance of rags and lint, a saucer containing a quantity of dilute acetic acid, and a stick of caustic potassa, we apply the latter with a firm hand to the diseased tissue in all directions. This melts down very readily before the caustic, and a little experience will enable one to know by the amount of resistance just when the healthy tissue has been reached. Complete destruction of the diseased parts being now accomplished, we lay aside the caustic, and immediately apply a piece of lint soaked in dilute acetic acid. This neutralizes the effect of the caustic potassa, the effect of which would otherwise continue to extend through the healthy surrounding tissues. The momentary pain caused by the application of potassa is almost imme-

diately relieved by the dilute acetic acid. We now dry the surface of the wound, and apply a simple dressing of olive oil upon lint. This will be renewed twice daily, and the surface of the sloughing mass kept as clean as possible. When the slough comes away it will leave a healthy ulcer beneath, which will heal rapidly. As it is often unadvisable or impossible to reach every portion of the diseased tissue at one application, we may find, when the wound heals, one or two small nodules still remaining. A subsequent application will suffice in that case to remove the last traces of the affection, but a deep scar will remain to mark its former seat.

EXTENSIVE ULCERATING SYPHILODERM.

The affection which involves this patient's leg is a chronic one; she tells us she has had it four years. The first thing we notice about it is its peculiar and disgusting odor. This at once excludes several diseases, and will aid us in our diagnosis. The discharge from the ulcers is profuse as well as offensive, for these rags, which our patient tells us were applied freshly this morning, are already soaked with the products of supuration. Examining the limb more closely, we see that there is a large area of disease, covering the front and sides of the whole leg, and involving the knee and part of the thigh. It consists of cicatricial tissue, patches and bands of inflammatory deposits, together with ulcers of various sizes, usually small. Around the outer and upper edges of the diseased skin a sort of advanced line of ulceration is slowly extending and forms a complete border to its upper portion. Without going into the various diagnostic signs, I shall state that this is an ulcerating syphiloderm.

The treatment of a case of this kind is simple. Having thoroughly established our diagnosis, we shall order the patient the most nourishing diet attainable, and, in addition, the iodide of potassium in the doses of ten grains three times a day. As an external application we shall order the following:

R Unguent. hydrargyri, ʒi;
Emplast. simplici, q. s.—M.

The object of the plaster is to give consistency to the ointment, and the proportion may vary according to circumstances of temperature, etc. This is to be spread upon small pieces of soft rags and placed over the ulcers, avoiding contact with the surrounding skin. The application may be made twice daily, or oftener, and the ulcers should be kept as clean as possible.

TRANSLATIONS.

ACCOUCHEMENT IN A PATIENT WHO HAD SUBMITTED TWO YEARS PREVIOUSLY TO GASTROTOMY.—Dr. Fourrier communicates the following case to the *Bull. Gén. de Thér.* for January 30:

The operation for gastrotomy which had been performed by himself was reported in the *Bulletin* for August 15, 1872. It was undertaken for the relief of rupture of the uterus with passage of the fœtus and appendages into the peritoneal cavity.

Since the time of this operation the general health of the patient had been as good as possible. She had been obliged, however, to wear an abdominal bandage, in order to support a threatened hernia of the intestines at the point of cicatrization.

Becoming again pregnant in 1873, the patient was removed, when the time for her confinement drew near,

to the hospital, where her accouchement was accomplished, August 15, 1874, without any accident. At the moment when the pains assumed an expulsive character, the hands of an assistant were employed in supporting the cicatrix, in order to keep the intestines in place, while Dr. F. himself supported the uterus.

The fortunate termination of this case is especially worthy of record, says Dr. Fourrier, since in similar cases the production of abortion at an early date has been suggested. Even in the present instance, indeed, the question was discussed.

To watch the labor, and to terminate it by version or by the application of the forceps in case it becomes too long delayed or too painful, should be, Dr. F. thinks, the duty of the physician, and he feels that in the case just described he has reason to congratulate himself on not having interfered too precipitately.

X.

ACTION OF CONIUM UPON CUTANEOUS SENSIBILITY.—M. Gubler reported, at a recent meeting of the Société de Thérapeutique, certain facts which show that hemlock modifies sensibility, and called attention in particular to the well-known phenomena attending the death of Socrates, and the observations recorded by Hunter, where a man who had taken a large dose of hemlock had lost the use of his fingers. He then went on to relate a case coming under his observation, where this action upon sensibility had been most evident.

It was that of a woman who had applied a pomade containing conium, with the fingers of her right hand, to a tumor of a cancerous nature situated upon her husband's body in the region of the liver. After a time, the fingers which had been used in making the friction lost their sensibility. The woman then ceased using the right hand and employed the left, covered with a glove; but in spite of this the fingers lost sensibility. All these symptoms disappeared rapidly upon ceasing the employment of the ointment.

Dr. Gubler draws attention to this fact in order to show the reality of those modifications of sensibility brought about by conium, a proposition which he had already recorded in his "*Commentaires de Thérapeutique.*"—*Bull. Gén. de Thér.*, January 30, 1875.

X.

A CASE OF HYSTERICAL HEMIPLEGIA (Dr. W. Svetlin: *Wiener Med. Presse*, No. 4, 1875).—The patient, a single woman, æt. 24, on the 12th of November, 1873, was exposed to cold just at the close of a menstrual period, consequent upon which she had spasms of the entire body very similar to those which result from poisonous doses of strychnia. Other symptoms of affections of a nervous character came on, and lasted for some time, but a gradual improvement took place which continued until February, 1874. On the 10th of the month, the patient, upon the receipt of news of a startling character, sank on her chair in a condition of unconsciousness. On the next day it was found that there was total paralysis of motion of the right side, with a diminution of sensibility.

About the end of March, treatment of the paralysis with the induction-apparatus was commenced, and after forty sittings there was some improvement in the motion of the upper extremity, and the voice, although still unintelligible, became more sonorous. From July the use of electricity twice a week was continued, and hydropathic treatment was also employed. The patient was twice a day rubbed down in baths the temperature of which was lowered one degree daily. By the end of the month, the patient was able with but little assistance to walk about the garden of the establishment, dragging the right foot but slightly, and could even go up stairs.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MARCH 13, 1875.

EDITORIAL.

THE WORK OF THE SURGEON-GENERAL'S DEPARTMENT, U.S.A.

A RECENT visit to Washington has afforded us the opportunity of overlooking the work which is being done under the fostering care of Surgeon-General Barnes; and it is with pleasure that we express our extreme satisfaction therewith. The forthcoming volumes of the "Medical and Surgical History of the War of the Rebellion" will, we believe, excel in general value their predecessors. The report now in preparation by Dr. Ely McClellan on cholera bids fair to be one of the most remarkable and exhaustive memoirs of the kind ever published. Dr. Billings is building up, with marvellous celerity and cheapness, what will soon be one of the world's great medical libraries. He has undertaken and made considerable progress in the colossal task of preparing a subject-index of medical periodical literature of this century. As the library now receives all the medical journals of the world, with the exception of a few obscure periodicals published in Greece, Spain, and Mexico, Dr. Billings has at hand the complete material for at least the recent times. All original papers are catalogued, not by their titles, but by their actual subjects, Dr. Billings himself looking over the papers and inserting the references to them. The extreme value of a catalogue of this character is at once apparent, but the labor involved is so enormous that, with the small number of assistants allowed by the funds, a long time must elapse before it is completed. Moreover, the literature of the later portions of the

century is by far the most important. We therefore sincerely trust that the catalogue will be finished by decades, beginning with the present, and will be published as fast as completed; otherwise we fear that our grandchildren will have more interest in the work than we have. The remuneration, direct and indirect, which these busy workers for our profession receive from the United States Government is absurdly disproportionate to the services rendered, and it is with great disgust that we learn of the adjournment of Congress without anything having been done for them. The Republican party, having attained power by the successes of the army, have turned it out to starve like a worn-out war-horse. We trust that if the Democrats get a turn at the wheel they will do better.

LEADING ARTICLES.

SALICYLIC ACID.

IN the *Journal für Praktische Chemie* for July, 1874, Prof. Hermann Kolbe published an article upon a new method of obtaining salicylic acid, and some of its remarkable properties, which, apart from its interest to chemists, contains much to attract the attention of others. After describing his new method for the production of the acid, which consists essentially in treating a solution of phenol in caustic soda with carbonic acid under the influence of moderate heat, Prof. Kolbe passes to what he terms the physiological effects of salicylic acid, which, up to the time that his new method placed it within easy reach of all, had been studied only by Berlagini, who found that in large doses—six grammes in two days—it produced singing in the ears, and that during its passage through the body it was partly changed into salicyluric acid, which, together with some unaltered salicylic acid, was found in the urine. In an experiment performed in the Leipsic Hospital it was found that when 0.3 gramme was given by the mouth the acid made its appearance in the urine at the end of two hours, and was still recognizable in that excretion at the end of twenty. As salicylic acid is, by the new process, made from carbolic acid and carbonic acid, and as by heating above the boiling-point it splits into the same substances, Prof. Kolbe thought it probable that it might have an antiseptic action and interfere with the processes of fermentation and putrefaction. The experiments undertaken by himself, which he is still busily engaged in prosecuting, and those of others, seem to show undoubtedly that he has discovered a very important addition to the armamentarium of those who are interested for any reason in combating the action of these processes. We give below a summary of the results so far published in the numbers of the above-named journal for December, 1874, and January, 1875.

Prof. Kolbe has found that the presence of salicylic acid prevents the formation of hydrocyanic acid in an emulsion of sweet and bitter almonds, as also the formation of the characteristic volatile oil which usually results on wetting mustard; also that, added to a solution of grape sugar containing yeast, it prevents fermentation, as it does also in beer. In an experiment upon milk, he found in the summer at a temperature of 30° C. (86° F.) that fresh milk to which a 0.04 per cent. solution of salicylic acid had been added became sour thirty-six hours later than another specimen to which no acid had been added. Added in this proportion, the acid imparted no taste to the milk. Urine to which it was added did not decompose.

He has also instituted some experiments as regards its power of preserving meat, eggs, and other articles of diet, as well as water, several casks of which he has stored away after adding varying quantities of the acid to them. The salicylate of sodium does not answer the same purpose, though Prof. Kolbe was led to experiment with it by the idea that when an acid was produced, as in the souring of milk, any base with which the salicylic acid was combined might be of service in neutralizing it.

Neubauer asserts, as the result of an interesting series of experiments performed by him, that we have in salicylic acid a means for controlling fermentation in urine, and a substance which is likely to be of inestimable value in the future.

Dr. Miller, a pharmacist, has compared the antiseptic properties of carbolic and salicylic acid. According to him, one part in 1000 of either will stop fermentation in grape sugar; one part in 2000 of salicylic acid is also effective; while this proportion of carbolic acid has no action whatever. In milk containing 0.04 per cent. carbolic acid, the latter is readily perceptible to the taste. It becomes sour, however, as readily as another specimen to which nothing has been added. Salicylic acid as noticed by Kolbe gives in this proportion no taste to the milk, and at the high temperature of 86° F. retards its souring notably; at lower temperatures its preservative action lasts much longer.

When, however, two specimens of the same urine were exposed to the air, one containing carbolic acid and the other salicylic, he found that a much larger quantity of salicylic acid was needed to prevent putrefaction than of carbolic acid. Salicylic acid in the proportion of one per cent. checks the action of ptyaline upon starch. To produce the same effect, ten per cent. of carbolic acid is needed. So in an experiment upon glycerin he found that while ten per cent. carbolic acid was needed to prevent the formation of sugar, 0.5 per cent. salicylic acid was enough for the purpose. It is worthy of special notice that the same observer found that while 0.2 per cent. carbolic acid does not interfere with the digestive action of pepsin, 0.2 per cent. salicylic acid interferes to such an extent that he concludes that a solution containing 1 : 1000 destroys three-fourths of the digesting power of an artificial gastric juice. This experiment carried on outside the body

does not, apparently, agree with the experience of Prof. Kolbe, who, in order to satisfy himself and others as to the effects of internal administration of the acid, took for several days in succession, in four portions, 0.5 gramme in watery solution 1 : 1000 without any ill or other consequences whatever. He then intermitted taking it for a week, at the end of which time he took one gramme a day for five days, and then on two successive days 1.5 grammes. These last portions were taken in a liquor which he compounded for the purpose, and which was then made use of by eight of his assistants and students, who took on one day one gramme, and on the next 1.5 grammes each, making in all twenty grammes, yet in no case was the slightest abnormal symptom observed. The urine and fæces of all were carefully collected, and we are promised the results obtained by the investigation of them.

Prof. Kolbe remarks with regard to his first experiment that throughout the time digestion was perfectly normal, and no unpleasant sensations were experienced. In the urine the acid was readily detected on the addition of the chloride of iron (which gives a violet reaction) after a precipitation of white phosphate of iron, but no trace of it was found in the fæces. Prof. Kolbe also, in order to test how far the acid could be absorbed through the skin, prepared a warm bath at 93° F., containing 250 kilos water in which 250 grammes of salicylic acid had been dissolved. In this he remained ten minutes, experienced no unpleasant sensations, and, as was perhaps to be expected, found no positive evidence of the presence of the acid in the urine passed during the rest of the day.

He now proposes to experiment by giving the acid to children before vaccination and during the course of the disease, in order to see whether the lymph obtained from such cases still retains its procreative power. This idea is the result of a conversation between himself and Prof. Beneke.

To pass now to the observations of medical men. In the service of Prof. Thiersch at the hospital in Leipsic, the acid has been found to remove foul odors, and the use of a solution containing one part salicylic acid, three parts phosphate of sodium, and fifty parts water, was found favorable to the healthy growth of granulations.

An operation was performed where salicylic acid took the place of carbolic acid. A spray was used 1 : 300, and the dressing was composed of charpie filled with crystals of the acid, and moistened with the 1 : 300 solution, which was afterwards used for irrigation at the rate of eight drops a minute. The case had a speedy and successful termination. The acid was found in the urine. From these and other experiments it is concluded that, as far as can be seen, salicylic acid has the beneficial effect without the disagreeable smell and poisonous character of carbolic acid. Dr. Fehling reports from the Gynæcological Institute of Prof. Credé, that in their practice they have found it of service used in solutions varying from 1 : 300 to 1 : 900 water, and in powder one part mixed with five parts starch, and promises a more

complete account in the *Gynæcological Journal*. Dr. W. Wagner, of Friedberg, has tried it during the last six months in all such cases as are generally benefited by carbolic acid. He finds that it renders the discharges from recent and chronic ulcers inoffensive. Using it first as an ointment—one part salicylic acid to fifteen parts lard—he found it unsatisfactory, and so had an ointment made by dissolving 1.5 grammes acid in three grammes alcohol, and mixing this with fifteen grammes lard, thereby securing a very efficient preparation.

Having been pleased with its action externally, he proceeded to apply it to two classes of cases: 1, those in which disease of the stomach or intestines is associated with abnormal fermentation of their contents, under which head he treated a case of cancer of the pylorus, which was rapidly approaching a fatal conclusion, and rendered the last days of the patient comparatively comfortable, checking the putrefaction of food, and consequent vomiting. He gave in this case 0.5 gramme in powder three times daily, and found the same dose of decided service in a case of chronic intestinal catarrh. In two cases of severe diarrhœa in children he gave a child one year old 0.05 gramme, and to a child three years old 0.1 gramme every three hours, in powder, with gratifying benefit. No more satisfactory result has been obtained than by Dr. Wagner in fifteen cases of diphtheria, of which more than half were of decided severity, and none really light. In the treatment of these, to children not able to gargle he gave 0.15 to 0.3 gramme in powder, mixed in water or wine, every second hour, and in addition caused those who were able to make use of a gargle containing 1.5 grammes dissolved in 15 grammes alcohol, and mixed with 150 grammes distilled water. If in this crystals formed, they were readily dissolved by gentle heating.

Of these fifteen cases none died,—a result more favorable than he had expected from the character of the disease at the time, and in all the duration of convalescence was much shortened, being in the mild cases from three to five days, and in the severe at most eight days.

It is to be remarked that Prof. Kolbe advises against the internal administration of the acid in the form of powder, as he has found that it attacks, to a certain extent, the mucous membrane of the mouth, œsophagus, and stomach.

Experimentation with this new agent is to a great extent in its infancy even in Europe, and it is to be hoped that some of our chemists will soon place it in the power of our physicians to see for themselves how far what is hoped from it can be realized in practice.

If it be really—and there seems to be no good reason to doubt it—as good an antiseptic as carbolic acid, its freedom from odor and from poisonous properties gives it an incalculable advantage over the latter, which will not be lost even if as a remedy in disease it may not be as Prof. Kolbe seems to expect.

H. B. H.

LEIPSIC, February 8, 1875.

CORRESPONDENCE.

NEW YORK, February 15, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—At a recent meeting of the Society of New York County, Dr. Simon Fitch, of this city, who has made an improvement upon the old trocar with especial reference to ovariectomy, aspiration, and transfusion, read an excellent paper upon the subject, of which the following is a synopsis.

The trocar, formerly seldom employed, he said, and of little value, has within the last few years become one of the most important instruments in the surgeon's armature, and is at present in almost constant use.

Many diseases and ailments for the detection and cure of which the trocar is now generally used are situated in or adjacent to either the lungs, heart, brain, spinal cord, abdominal viscera, pelvic organs, or the great joints; and where it is considered that these vital and sensitive structures require solicitous protection against all mechanical injury beyond what is essential to the discovery and extirpation of their diseases, it will be evident that the instrument used, whether for exploration or treatment in or upon such parts, should be—

1. Easy of insertion, so that it may not bruise, lacerate, or stretch the walls of the cavity to be entered, nor disturb the connections or relationships of the neighboring parts.

2. Harmless when inserted, so that it shall not injuriously abrade; does not scratch or puncture the interior of the cavity or adjacent structures.

3. Competent to give the freest possible exit, consistent with its size, to the fluids which are to be discharged.

4. Apt to leave, upon withdrawal, such wound as will most readily heal.

The old trocar, with its canula fitting more or less loosely behind the triangular head, is a clumsy and dangerous instrument. The aperture made by the point of the instrument is forcibly dilated by the bulging occiput of the trocar-head. Then the split end of the canula does not pass in smoothly, but, as it is expanded in being pushed forward over the head of the stylet, is liable to get entangled in the tissues at the edges of the triangular aperture, and so fail to enter perfectly, or, if forced in past the obstruction, the orifice is still further stretched and the edges irritated, or perhaps lacerated; and upon withdrawal of the instrument there is left a jagged, punctured wound, indisposed to heal by the first intention.

In 1850, Sir James Y. Simpson had the head of the stylet reduced the same size with the shaft, so that it should stretch the orifice less, and, as the canula could then be advanced without spreading, he omitted the split in the end; and at the same time he announced his employment of a long, slender trocar, with an exhausting syringe attached, as a means of diagnosis in various internal enlargements, especially in pelvic tumors, and so initiated the idea which Dieulafoy subsequently elaborated into his admirable aspirator.

The idea of making the canula itself pointed, so as to penetrate independently of the stylet, was first suggested in 1853, by Fergusson of London, who contributed a pen-like tubular needle for injections of the perchloride of iron in the treatment of nævi and aneurisms. In 1858, Dr. Alexander Wood, of Edinburgh, adapted this instrument to the subcutaneous injections of morphia, and a modification of the same instrument is now in universal use.

Spencer Wells shortly afterwards enlarged this little tubular trocar for ovarian tapping, and made the edges of the pointed end sharp and cutting for one-half the circumference of the tube, whereby a semilunar cut is made (if sharpened all round it would cut out a circular piece and leave a round hole), and he added a sliding outer canula, which, upon puncture being effected by the cutting point of the inner tube, is pushed forward as a guard against further action of that point.

This instrument, superior in many respects to the old trocar and canula, especially in respect of the wound made by it being incised rather than punctured, has still, in common with it, this grave fault, that the protecting tube is on the outside, and if made thin, so as to pass more easily into the aperture made by the point of the inner tube, the open end becomes a cutting edge, dangerous to the interior of the cavity and to the contained or adjacent viscera, as the bladder, when the contents are discharged by puncture, or the heart in tapping of the pericardium, or the lung in paracentesis thoracis, or the intestines in tapping for ascites. (The outer tube is sometimes obtusely rounded, so that it may enter more easily, but this makes it more dangerous to the interior.)

But if the terminal edge of the outer tube be blunted or made thicker, so as better to protect the interior, then it necessarily presents a resisting margin or shoulder outside and behind the point of the inner tube, liable to catch and carry before it the sac, or the immediate investment of the cavity, and so fail to enter properly.

Now, this accident may occasion considerable inconvenience, or even be productive of great harm, in cases of simple tapping, or for hydrocele, when, if the tunica vaginalis is not very tense, it is oftentimes extremely difficult to get the outer canula pushed in over the puncturing end; and in empyema, with a thick and tough pleura, so much force is sometimes required to urge the entrance of the outer tube as really to endanger a separation of the membrane from the ribs; and in tapping for the temporary relief of ovarian dropsy, if the outer tube do not follow the trocar quite into the cyst, or if in entering it catch or tear or split up a fragile cyst, more or less of the cystic fluid will escape into the abdominal cavity, which is one cause of the fatality that sometimes follows this simple operation.

But should *injection* be attempted with an imperfect introduction of the protecting tube, whether that tube be the canula of the old tube, or the outer tube of Wells's trocar, the result may be most disastrous.

The essayist had seen intense peritonitis occasioned

by tincture of iodine thrown upon the peritoneum in such an attempt to inject an ovarian cyst. And Syme, in his "Principles of Surgery," noticing the faulty injection for the cure of hydrocele, remarks, "If the liquid is allowed to remain in the cellular substance, it gives rise to violent inflammation, and soon terminates in sloughing of the scrotum."

Dr. Fitch had encountered on many occasions difficulties similar to the above, and in common with others tried to obviate the uncertainty of entrance of the outer canula, by cutting down to the peritoneum, or pleura, or tunica vaginalis, or whatever might be the immediate investment of the fluid to be evacuated, or the cavity to be entered, until it occurred to him to *reverse the relation of the tubes to each other*; and while in Edinburgh, in 1871, he had an instrument made by Gardner, upon the following plan: The outer tube, smooth and of uniform size, has the distal and pointed end cutting *like a lancet*, so that it penetrates easily, and to any depth, without the necessity of any previous incisions of superimposed tissues, and the protecting tube, being inside, may be advanced into the interior of the cavity with absolute certainty of entrance, and without the possibility of even touching the margin of the aperture or any of the tissues through which the outer tube has passed. The cutting portion of the puncturing tube should rise from the point not suddenly nor in a curvilinear form, but gradually, and in a perfectly straight line, making an angle of less than 45° with the pointed end of the tube, so that it shall enter by a clean incision, without injury to the aperture. The same year, instruments were made similar to the above by Krohne and Sesemann, and were exhibited at the next meeting of the British Medical Association in London, in August, 1873. The largest size is noticed in Spencer Wells's recent work on "Diseases of the Ovaries," p. 336. But the smaller-sized instruments seem to have been overlooked. Mr. Alfred Goodrich, in a letter to the *British Medical Journal*, August 8, 1874, says, "In emptying a cavity with the aspirator, the operator is often alarmed by finding the instrument filled with blood, arising from the walls of the collapsing cavity being forcibly sucked against the sharp point of the needle," and he proposes, as if it were his own idea, that the trocar consist of two tubes, the outer one pointed, the inner one not so. But in the same journal for August 22, Mr. George Brown, of the N. E. Hospital for Children, referring to Mr. Goodrich's suggestion of a trocar guarded by an inner tube, remarks, "The idea is not original. We have had one in constant use for more than twelve months, which was supplied us by Messrs. Krohne and Sesemann," who were the makers of Dr. Fitch's instrument in 1871, and which in the Catalogue of the Museum at the forty-first annual meeting of the British Medical Association is designated "Wells's Trocar, Improved by Fitch."

Yet this instrument is *not perfect*; for, although the certain entrance of the protecting tube is securely provided for against the possibility of failure, yet the open end of this same tube may itself be a source of danger,

especially in the aspirator trocar, when it must be made very thin to avoid bulk.

A very important modification of the original instrument covers the danger of an open canula, and makes it, while performing the ordinary purposes for which a canula is used, likewise available as an efficient and safe exploring probe or sound.

The distal orifice of the inner canula has been closed over by a rounded or dome-shaped roof, so that when it is projected beyond the cutting point of the outer canula the two tubes fit closely together, and the end of the combined instrument fits perfectly smooth, like the end of a sound or catheter, and may be freely moved within the cavity penetrated, without danger of wounding any viscera or organ, puncturing any vessel, or even scratching or abrading the tissues of the cavity, or any part contained therein. The base of this dome being of the same external circumference as the inner tube, and fitting the outer tube accurately, when the point of the instrument enters a cavity there can be no escape of the fluid till the dome is advanced, occluding the cutting point of the outer tube; thus there is disclosed a fenestra, or oval aperture, on the lower end, cut out of the lower wall, and two-thirds of the breadth of the side-walls of the inner tube, of the full size of the tube, and by which the fluid may be freely evacuated. The segment in the tube forming the distal end of the fenestra is sloped off, so that if a flake of pleura or accidental piece of tissue rest upon it, it will slip off as the instrument is withdrawn from the cavity. But the lip at the proximal boundary of the segment projects in a curve over nearly a third of the fenestra, so that the fenestra may not be obstructed by any substance in the cavity.

The trocar thus constructed is harmless to the parts requiring protection, and the fenestra, so guarded, and being, moreover, on the under side, cannot be stopped by the wall of the cavity coming into contact with it, as often happens to the open end of the old canula, by the falling upon it of any of the viscera or any layer of false membrane or fibrous septum; and if there be any aggregations of cyst, or a multilocular sac, the instrument may be employed as a probe or sound, or a long artificial finger, with which to feel for a proper place where it may be held until the cutting point is advanced to make an aperture for its introduction.

Thus, in ovariectomy it will be found extremely convenient, the left hand supporting the tumor, and the right holding the instrument, which can be instantly changed, by an easy movement of the same hand, from a trocar to a sound, and, *vice versa*, to define and puncture cyst after cyst, until the bulk of the whole is sufficiently reduced to admit of withdrawal through the abdominal incision, and with only one outer aperture in the sac first punctured, and thus always occupied by the instrument; and it may be here used where the end of the open tube could not be safely, to stir up and liquefy locular contents, and to break down such obstructions to the flow, while it still closes the original aperture, thus preventing the escape of the cystic fluid into the

cavity of the abdomen; and it may then obviate the necessity of enlarging the aperture in the cyst for the introduction of the hand.

Dr. Fitch thinks that the trocar may be used to advantage in the operation of transfusion. A trocar of suitable size being attached to each end of an india-rubber tube a foot long, one of the trocars is inserted into the vein which is to furnish the blood, and when the apparatus is filled, the other trocar is introduced into the receiving vein, and the operation is completed.

The advantage of the trocar in this connection is that, being smooth upon the end, the vessels may not be injured, and all the other evils attending the ordinary method of transfusion are avoided. The operation, moreover, may be performed quickly and with little trouble.

He uses also for ovariectomy, and in all operations where fluid of any kind is to be concentrated, a rubber tube, slipped over the end of the trocar, for the purpose of conveying to a proper vessel the fluids to which exit is given. By this means the clothing of the person or bed may be kept perfectly dry and clean.

The Society, after expressing their approval of the instrument, and thanking the author of the paper for presenting it, adjourned. W.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, JANUARY 15, 1875.

(Continued.)

THE PRESIDENT, DR. WILLIAM PEPPER, in the chair.

Hepatic abscess, opening externally in right side—Death from exhaustion.

DR. WILLIAM PEPPER exhibited the liver with portions of the lower right rib attached, with the following history of the case:

W. S., æt. 30, was admitted to the Philadelphia Hospital October 11, 1874. He was of intemperate habits, but had never had venereal disease nor dysentery. Had never lived in any tropical climate. Several years before, while in the army, he was wounded in the left side by a charge of duck-shot, part of which remained, but gave rise to no subsequent trouble. He first began to complain in March, 1874, of severe pain in the right side. This was at first paroxysmal, but soon became dull and continuous, and was attended for six weeks with hectic fever. This diminished, and soon there was noticed bulging of lower part of antero-lateral aspect of right thorax. The swelling extended around base of chest on right side, but was most prominent about seventh and eighth ribs in line of anterior border of axilla. Here it was, when it first appeared in June, very hard, but by August it had become softened, with indistinct fluctuation; and, on the 22d, eight fluidounces of pus were withdrawn by the aspirator by Dr. Tyson. The minute opening did not close, but continued to discharge pus quite freely. His general condition, under the use of tonics and nutritious diet, remained quite good for some time, but by October he began to lose ground decidedly. There was an ulcerated opening in eighth interspace, from which large discharges of pus occurred daily. A probe could be passed six inches

upwards and inwards through the intercostal opening. The liver-dulness began at sixth interspace, and extended to two inches below margin of ribs. Injections of various medicated liquids were used, but without any beneficial effects on discharge. Before December the tissues around the fistulous opening began to slough, and portions of the eighth and ninth ribs were exposed in a necrosed and roughened condition. His general condition grew rapidly worse, and death occurred on December 2.

Autopsy, six hours after death.—The ulcerated surface on the right side was seven inches long by five wide, extending from the sixth interspace above to the eleventh below. It was perforated by an opening in the eighth interspace, and by another some two inches in length in the ninth. Upon removing the sternum, nothing abnormal was noticed in the thoracic cavity, excepting an adhesion of the lower surface of the right lung, by slight cellular bands, to the diaphragm. No perforation of the thoracic cavity had taken place. Immediately below the diaphragm quite a large abscess was found occupying the right extremity and upper surface of the liver, the space between it and the diaphragm and right kidney, and communicating with the external opening.

Liver but slightly enlarged. Structures at a distance from the abscess fatty. Surface of right kidney ulcerated; its structure indurated and firm. No extended peritoneal involvement. The liver, diaphragm, ascending colon, and right kidney were firmly bound together, circumscribing the abscess.

Remarks.—This case presented several features of great clinical interest.

1. As to the locality of the abscess. The absence of the usual causes and symptoms of hepatic abscess, the previous severe pain in the right side, the point of rupture, and the physical signs, raised the question whether the case was one of circumscribed pyo-pneumothorax, or of abscess beneath the diaphragm. And the difficulty of determining this was increased by the close adhesions beneath the under surface of the right lung and the diaphragm, and the great degree in which the latter muscle was stretched upwards.

2. The question as to the starting-point of the disease. It might be regarded as possible that the disease had originated in connection with the rib; but a careful consideration of the case appears to render this untenable. It will be noticed that the hectic fever, which undoubtedly marked the occurrence of suppuration, preceded by some weeks the first appearance of external bulging. Again, the readiness with which a collection of pus forming in connection with the rib might discharge externally, renders it highly improbable that it could effect such extensive internal trouble before finding an exit through the skin. Abscess of the liver in rare instances arises in this climate idiopathically, or at least without recognizable cause, and it is very rare for the entire course of the disease to be unattended by any special symptom of hepatic disturbance. The post-mortem appearances of the liver, finally, show such a degree of destruction of its tissue as to indicate that the abscess originated in its substance.*

Dr. JAMES TYSON remarked that from his knowledge of the case as it existed while under his care, he could not feel altogether satisfied with the idea of the hepatic origin of the abscess. The almost stony hardness of the tumor of the side as presented when he first saw the case, the remoteness from the liver of its most prominent portion, as well as its apparent superficial position, all led him to suppose it was associated at its

beginning with disease of the ribs, although the traumatic nature of its origin as suggested by the patient was not entertained for a moment, as the gun-shot wound was on the opposite side. He had never suspected any relation of the abscess to the liver either primarily or secondarily.

Dr. PEPPER said that against the idea of its having started from the ribs were the facts that while the man had suffered from pain on the right side for months, and that while there was found so extensive a lesion internally, the external swelling presented itself a comparatively short time before its evacuation; and we must suppose that if it started externally, it had perforated, by ulceration, the diaphragm and the firm fibrous capsule of the liver, and had destroyed a portion of the liver three inches in diameter by one and a half inches in depth. These facts, taken in connection with the well-known phenomena of hepatic abscess, its occasionally latent character, sometimes advancing to rupture without having given any marked evidence of disease of the organ, seem to leave no other conclusion to be arrived at than that it was a hepatic abscess which had worked its way externally to the point described.

Dr. BERTOLET asked whether there were any evidences of embolic processes. Portal thrombosis being by far the most common cause of hepatic abscess, it is very important to ascertain the presence or absence of ulcerative and inflammatory processes in the intestines and gall-bladder; indeed, it is now denied by many that primary suppurative hepatitis ever occurs, but that the origin of hepatic abscess is by an embolus or foreign body obstructing a blood-vessel. Even traumatic affections of the liver only rarely lead to the formation of abscesses, and preferably when complicated by the presence of a foreign body.

Dr. PEPPER replied that no careful examination had been made to this end, but that while abscess of the liver, especially of the metastatic form, which is so frequent, was apt to be attended by a partial stasis or thrombosis, he could not think that embolism was the only cause of such abscess. In a number of cases which he had studied of hepatic abscess following dysentery, he had observed portal thrombosis around the abscess.

Dr. ALLEN said that in gun-shot wounds of the liver the pus therefrom was sometimes observed to have a peculiar color due to blood-staining, caused not so much, however, by the presence of blood as by its coloring-matter, hæmatin, or derivatives.

Head of the femur removed by excision in a case of coxalgia.

Dr. J. M. BARTON presented the specimen, from Mina F., æt. 10 years, with a decidedly strumous history; has suffered from the usual symptoms of coxalgia for the last fourteen months, suppuration beginning five months ago, the amount of discharge being quite moderate until the middle of December, when, the child having lost appetite and flesh, hectic fever having appeared, and the discharge from the sinuses becoming quite profuse, excision was determined upon.

"On December 22 I excised the head of the femur in the usual manner. The femur was found dislocated upon the dorsum of the ilium, as the deformity indicated. The acetabulum was free from disease, except a small portion of its lower margin, which was readily removed.

"The patient did remarkably well for two weeks. Appetite very good; bowels natural; no pain, and the discharge quite moderate in amount; but from this time she gradually sank, and died exhausted, January 11, twenty days after the operation.

"I have here also the upper extremity of the shaft of the femur, removed post mortem, showing the efforts at repair. It was nearly in contact with the acetabulum, and its attachments to the pelvis were quite firm."

* To this must be added the absence of any traumatic cause of necrosis of the ribs, and also the absence, as shown by careful examination of the patient's history, of any syphilitic taint.

Case of malformation of the nose.

Dr. FERDINAND H. GROSS, presenting the case, said that he had to exhibit the body of a male child born at term with a peculiar malformation of the nose. That the organ consisted of a mere cylindrical fleshy tube starting out from between the eyes or the position of the root of the nose, its dimensions being a little over an inch in length and about half an inch in diameter. That there was no cartilage of the septum nor columna, and instead of the two anterior nares there was but one small round opening or canal. It was quite soft and flexible, and bore a resemblance to the male organ of an infant.

Dr. Gross stated that the case had come to his notice under the following circumstances: That on the previous day, while visiting a case of frost-bite in the house of a midwife, the latter informed him that on the same morning a German woman, the wife of a butcher, had been unexpectedly taken with strong labor-pains while standing at her stall in the market, and that there had been only time enough to get the woman into the house of the midwife, which was in the neighborhood, when she gave birth to this child. She reported that it showed signs of life immediately, that it cried, breathed imperfectly for nearly an hour, and then died. The body was quite livid when first shown to Dr. Gross, and the cause of death was no doubt asphyxia.

The mother was twenty-four years of age, and had borne four healthy children.

The specimen was referred to a special committee, consisting of Drs. F. H. Gross, Harrison Allen, John Guitéras, and John M. Keating, for examination and report.

Cystic kidneys; obstruction by enlargement of the lateral lobes of the prostate gland.

Dr. W. H. PARRISH presented the specimen, for Dr. C. M. HARRIS. A. F., aged about 60 years, died January 10, 1875. He was seen by Dr. Harris for the first time one day before death, and no history of prior condition could be obtained. When seen, he was suffering with pelvic and abdominal pains, and pain down each thigh. He died in slight coma, without convulsions.

Autopsy, January 11, 1875.—There was general emaciation; slight atheroma of valves of heart. *Lungs* normal. *Liver* cirrhotic. *Intestinal tract* apparently normal. *Prostate gland* greatly enlarged and quite firm. *Bladder* contracted, walls much thickened and in a rugose condition; the openings of the ureters into the bladder were diminished in calibre. The *ureters* were examined only at their extremities; the upper extremities were dilated. *Pelvis of both kidneys* dilated, as were the calyces of both. In the pelvis of the left kidney and upper portion of the left ureter were about two ounces of muco-purulent fluid.

The parenchyma of both kidneys was diminished in quantity, as if atrophied from pressure.

Hermaphroditism.

Dr. JOHN M. KEATING exhibited the specimen, which was referred to a special committee, consisting of Drs. Keating and Harrison Allen, for report. The Committee reported, January 28, 1875, as follows:

"Your Committee to whom was referred the specimen of hermaphroditism exhibited by Dr. J. M. Keating have to report that, upon examination, the *uterus* and ovaries were found in position, not presenting any abnormal conditions in regard to shape and development. Immediately in front of them was seen the bladder, much contracted by the action of strong alcohol used to preserve it: it had assumed the character of a solid tumor before it was opened. *Ureters*, although somewhat torn, were easily traced, a probe passing readily through them. The relations of the urethra

were normal. After careful search, neither testicles nor any trace of them were found within or without the abdominal cavity. Externally, the labia were much enlarged. The clitoris, though probably much contracted by the strong alcohol, was about the size of the penis at term. The anterior orifice of the vagina was obliterated by a true integumental growth, which was continuous with that of the perineum.

"Your Committee therefore conclude that the specimen belongs to the class of spurious hermaphrodites characterized by the presence of true female organs conjoined with excessively developed external organs and imperfect development of the vagina."

Lipoma.

Dr. JOHN ASHHURST, Jr., exhibited a large fatty tumor removed from the left infra-mammary region of a male adult. The growth was, as is usual with tumors of this nature, surrounded with a distinct capsule, which sent off prolongations, forming septa which separated the several lobes of the mass.

Scirrhus cancer of pancreas, liver, and lung; hydatid cyst of liver.

Dr. H. R. OSGOOD presented the specimens, and read the following history: "The organs which I have the honor of presenting to the Society were taken from the body of a female, *æt.* 81. I was called to this person shortly before her death. Found her in great discomfort, the painful symptoms radiating from the vicinity of the stomach. Patient referred her pain to a spot somewhat at the left of the median line, but in the epigastric region. Pressure revealed the greatest sensitiveness in the median line an inch or two below the xiphoid cartilage. The patient was annoyed by constant vomiting, and was unable to retain either food or drink. It was principally with reference to this symptom that I had been called, for the pain just mentioned, although constant, was not excessive. It was only when I resorted to palpation that it became unbearable. Percussion also created such distress that because of the advanced age and great debility of the patient, and especially since I saw she was sinking, I refrained altogether from any attempt to establish a diagnosis, and directed my attention to the relief of the gastric symptoms. Under the influence of bismuth and morphia the vomiting ceased, and a fair amount of milk and lime-water, as well as beef-tea, was taken for a short time. Wines, including champagne, were not kindly borne. The heart pulsed normally. I discovered a mild bronchitis, which accounted for the patient's cough. There was obstinate constipation, which was relieved by enemata. After a day or two of the improved condition of the stomach, the patient again refused food of every sort. Injections of beef-tea were administered without avail, and she passed quietly away. I regret that my clinical details are so meagre; yet, under the circumstances, I felt justified in sparing the patient what would have been a painful examination. She was in a too prostrated condition to give me her history. Her immediate attendants simply knew that she had been treated for dyspepsia during the past summer at the Woman's Hospital. It was not until after her decease that I had the good fortune to learn some details of her history from a lady to whom the patient had several months ago related them. It seemed that the deceased referred the beginning of her illness to a day so long as twenty-five years ago, when she was engaged upon her son's farm in gathering stones, which she removed by the help of basket and apron. She had filled her basket, and then proceeded to fill her apron, the end of which she held in one of her hands. Upon lifting her basket with the other hand she suddenly felt something give way in the vicinity of her stomach. She fell senseless to the ground, and was carried to her bed, in which she re-

mained for a period of eight weeks. Subsequently she labored constantly, but with less strength and vigor than formerly. Excepting that the patient never entirely recovered from the effects of this occurrence, I could learn nothing concerning her health during the seventeen years which intervened between this and another injury which the patient received in falling down a flight of stairs. This was eight years ago. She was again taken up senseless, and again confined to her bed for several weeks. Patient thought this fall aggravated the original injury, and never felt well thereafter. Previously a very stout person, she became much reduced in weight. She frequently said there was some internal derangement, and, curiously, imagined that her 'sweet-bread' was involved. She was familiar with the anatomy of the pig, and hence her remarkably correct supposition. The remitting symptoms of her ailment during the past eight years were great restlessness, irregularity of appetite, frequent vomiting of food, pain in the epigastric region, obstinate constipation. These data of her complaint became so severe in the early summer of last year as to lead her to seek aid at the Woman's Hospital, where a physician examined her with great care and finally pronounced the difficulty a violent form of dyspepsia.

"The friends of the patient consented to a post-mortem examination of the body. There was marked emaciation, but no external signs of injury. Heart somewhat atrophied, its muscular tissue flabby, valves normal. Slightly atheromatous condition of the ascending aorta. Left lung in a fair condition. Right lung bound down by pleuritic fibrous tissue of great age and immense strength, besides which the antero-posterior far exceeded the lateral diameter of the thorax. I could have removed the lung only by slow dissection, and, having only half an hour for the entire examination, was obliged to leave the lung in position. I could see, however, that it was studded with pale-yellow nodules, varying in size from that of a pea to that of a filbert. I cut off a slice of lung containing one of these nodules, and have since examined it under the microscope. Upon uncovering the liver, I found its upper and anterior surface studded with projections varying in size, and of a color somewhat lighter than that of the surrounding hepatic tissue. Removed the liver, and found these nodules generally distributed throughout the organ. The whole liver was atrophied, especially the left lobe, in the lower border of which were fine specimens of scirrhus degeneration. In the same lobe and same situation, but nearer the longitudinal fissure, I found a beautifully-proportioned cyst one and one-half inches in diameter. Its walls consisted of firm fibrous tissue. It fluctuated but slightly. If I had then known that I would be permitted to take possession of these organs, I should have left the cyst intact for the observation of the Society. I opened it, and there exuded not fluid, but a thick cheesy matter, followed by a jelly-like mass of friable consistence. The cheesy matter occupied one-third of the interior of the cyst, and completely surrounded the gelatinous mass which filled the centre. The gall-bladder was distended by one large calculus. Removed the stomach. I found its internal surface in a condition of chronic hyperæmia, and abundantly covered by a catarrhal secretion. No contents; color dark brown; otherwise normal externally as well as internally. I next sought for the pancreas, in the place of which I found a large solid mass attached to the spinal column. I removed it, together with the spleen, which came with it. Latter organ small and normal. Cutting into what I supposed to be the pancreas, but which was a shapeless mass, lacking the tail of that organ, my knife gave the "cry" characteristic of scirrhus tissue. In the mesenteric fat about it, were curious coils of calcification. Further than this I did not

examine, except to see that the kidneys were normal. I saw that these organs presented the rare combination of scirrhus cancer and hydatid, and finally prevailed upon the friends of the patient to allow me to take them away. I regret that I was forced to leave the right lung. Upon subsequent examination of the contents of the cyst, I found in the jelly of its centre an occasional hooklet, crystals of cholesterine, débris of various sorts. It is then a hydatid cyst in a condition of fatty degeneration. I did not examine the cheesy matter, not deeming it necessary.

"The embarrassing feature of these organs is the condition of the pancreas. What I supposed to be its body and head, upon further examination suggests an enlarged mesenteric gland. I do not find the head of the pancreas. This mass is on the left of the aorta (which, I may remark at this point, is atheromatous and calcified). The superior mesenteric artery plunges into this mass, turns upon itself, emerges half an inch from its point of entrance, and terminates in the calcified loops already mentioned. I have indicated its course by a bit of cord. The splenic artery leaves the aorta (for there seems to be an extremely short coeliac axis) and runs straight to the left. But, while in its normal relation the artery passes along a groove in the upper border of the pancreas, in the specimen under consideration it passes outside the lower fourth of the mass posteriorly. Its left cut extremity, however, lies directly above a tissue which may suggest mesenteric fat, but which, judging from a very brief microscopic examination, I am inclined to think is pancreatic,—probably the remains of the tail of the pancreas.

"On the other hand, the splenic vein, which normally pursues the same course as the artery, but in an opposite direction, coursing below its artery, begins at its splenic end in proper relation to its artery, viz., below it. Its course, however, takes it above the artery, and it finally plunges into and through the very centre of the fibrous mass at least an inch above the origin of the splenic artery. I have indicated the course of both artery and vein by straws. So much for the hints given by these vessels. The main question seems to be, Where is the pancreas? A portion of its body and tail is, I believe, to be seen. But the head has disappeared, and the fibrous mass lies to the left of the abdominal aorta, the proper position of the head of the pancreas being on the right of that tube. The fact that the superior mesenteric artery forms its first loop in the substance of the fibrous mass would seem to be a proof that this mass is an enlarged gland. But in its very centre we find the splenic vein, and at its left border pancreatic tissue. May not this body have taken up the head of the pancreas as well as the splenic vein? Concerning its actual situation in the body of the patient, judging from its relation to the abdominal aorta and such of the pancreatic tissue as we find, it may be taken for granted that it lay a little to the left of the normal site of the head of the pancreas, but that, while a portion of its bulk occupied a plane somewhat above the normal level of the body of the pancreas, its main bulk took the place of the body and angle of that organ. As already mentioned, the splenic artery at its left extremity lies upon pancreatic tissue, and immediately in connection with the tissue was the spleen, which I removed and left behind. This residue of the pancreas appears to extend directly into the fibrous mass at the right. I have refrained from mutilating the mass beyond the original cut, thinking it would be more instructive if I left the specimen as it is, for the inspection of the members, hoping it would then be referred to the Committee on Morbid Growths for further examination.

"After I had gained the unexpected permission to take the organs away, I sewed up the hydatid cyst with its

contents and restored it to a condition which will sufficiently indicate its original appearance.

"The small nodule which I removed from the lung, I have examined under the microscope, and find its structure similar to that presented by the nodules in the liver. The combination of conditions shown by the specimens is rare. We have cancer of the lung, cancer and hydatids in the liver (I cannot say there was no hydatid in the right lung), and a condition of the pancreas which demands further study. In regard to the cyst, I would call attention to the fact that it existed in the body of a person eighty-one years of age, which is very unusual. According to Budd, hydatid tumors are so rare in the aged that he limits them to the years of life between six and fifty. The oldest of Frerichs's hydatid-patients was sixty-five. Davaine finds this form of tumor between the ages of twenty and forty. Single hydatid cysts are also very rare in the left lobe of the liver.

"I will add merely that the specimens have been kept in a fifteen-grain solution of chloral, and have, I think, retained their original color, consistency, and freedom from odor more perfectly than would have been possible in any other preservative."

PHILADELPHIA COUNTY MEDICAL SOCIETY.

AT a conversational meeting held Wednesday, December 23, 1874, at 8 o'clock P.M.,

THE PRESIDENT, DR. W. L. ATLEE, in the chair,

DR. O'HARA exhibited a patient he had attended some six months previous with an injury about the cervical vertebræ, supposed at the time and for two weeks after to be a fracture of the odontoid process. That opinion was afterwards given up, but at this time some trouble remains which he considers to have been caused by laceration of the atlo-axoid ligaments. Opinions as to his present condition differ, and he introduced the case as one in which there was some obscurity, and would like to have an expression of opinion from the members present. It was one of those cases where opinions are given in court diametrically opposite, and lead to prejudice against the profession.

Prof. H. H. SMITH, after an examination of Dr. O'Hara's case, thought the odontoid process could not have been broken. No authenticated specimen of such fracture had ever been found, and the few cases reported were from extreme violence; this patient, from his present symptoms, had suffered probably a fracture of the fourth spinous process of the cervical vertebra, and he had also an enlarged bursa, or movable body, under the muscles and fascia of the back of the neck.

Dr. W. L. ATLEE, after an examination of Dr. O'Hara's case, said that he did not think it a fracture of the odontoid process. The small protuberance was too low down to indicate an injury at that point, being full one and a half inches below the axis vertebra. Neither could he make out a fracture of the spinous process of any of the cervical vertebræ. He thought the primary symptoms may have resulted from shock, and the subsequent ones from inflammation and its results, and that the small movable knot on the back of the neck was not a portion of detached bone, but an enlarged bursa.

Dr. O'HARA asked if any gentleman could give his experience in monobromide of camphor. In one or two cases of approaching delirium tremens in broken-down subjects, he administered it in three-grain doses every two hours, and after a few doses seemed efficacious in inducing sleep.

Dr. H. C. WOOD, in reply, said that our knowledge of the action of this drug is very limited and uncertain.

Dr. J. M. BOISNOT then read a paper,—subject, "A Case of Purpura Hæmorrhagica requiring Transfusion."

Dr. WOOD said he was interested in the paper, and asked Dr. Boisnot his grounds for so referring the purpura to a fall.

Dr. BOISNOT considered that such an accident might be referred to as a remote cause for want of a better; the child had never been ill during the interval.

Dr. ATLEE asked Dr. Boisnot whether the full amount of four ounces of blood had been introduced, and what was the time consumed in injecting it.

Dr. BOISNOT replied that the amount transfused was four fluidounces, and the time about two minutes.

Dr. ESHLEMAN asked whether there was much blood lost by epistaxis.

Dr. BOISNOT said there were about ten attacks of epistaxis.

REVIEWS AND BOOK NOTICES.

A SERIES OF AMERICAN CLINICAL LECTURES. Edited by E. C. SEGUIN, M.D. Vol. I. No. 1.

This lecture, by Professor Louis A. Sayre, on Diseases of the Hip-Joint, is the commencement of an indefinite series, whose number we suppose will be governed by their success, in imitation of the famous Alkmann Sammlung Klinischer Vorträge. Of course, no better selection could have been made than that of Professor Sayre to write the lecture upon hip-joint disease; but, as all the names as yet announced as contributors are those of New York physicians, we are tempted to suggest to Dr. Seguin that Gotham, though it has produced three wise men, is not America, and that if he really desires to do justice to American medicine and to do all in his power to secure practical success to his undertaking, he should widen his horizon. The typographical appearance of the lecture is very creditable to its publishers, whose efforts we trust will be sustained by the profession.

THE MICROSCOPE AND ITS REVELATIONS. By WM. B. CARPENTER, M.D. Fifth Edition. Philadelphia, Lindsay & Blakiston, 1875.

We are always glad to see an American imprint upon an English-printed book, as we take it as an indication that the author has got, or is to get, at least some compensation from his American readers. Either because the book deserves it or because we are influenced by natural prejudices towards the favorite source of our early knowledge, we deem this work of Dr. Carpenter's the best general work on microscopy in the language; and a somewhat cursory examination of our old favorite in its new dress indicates that it has been in all respects brought thoroughly up to the times.

REPORT OF THE HEALTH COMMISSION OF THE STATE OF NEW JERSEY, 1874.

The pamphlet before us is one of the many indications that our various governments are beginning to appreciate the value of State medicine. The Commission was a preliminary one, and the result of their labors has been to bring forward a proposed law, modelled after that of Massachusetts, for the formation of a State board of health. The arguments they offer in favor of this or some similar enactment are unanswerable except by the passage of the law, which we trust will take place this winter.

EATING FOR STRENGTH. By M. L. HOLBROOK, M.D. New York, Wood, Holbrook & Co., 1875.

The chief value of this book, if value it have any, consists in the receipts contained in it. As our cook has

not found time to test these as yet, we offer no opinion concerning them. The book, however, comes in such questionable form that we do not think the profession will be committing hari-kari in practising towards it total abstinence. In justification of this remark, we would state that the title-page informs us that the author is the editor of *Herald of Health, Parturition without Pain*, etc.

GLEANINGS FROM OUR EXCHANGES.

MANUAL DILATATION OF THE OS UTERI AS A MEANS OF INDUCING PREMATURE LABOR (*Boston Medical and Surgical Journal*, February 4, 1875).—Dr. A. D. Sinclair strongly recommends the use of the hand of the obstetrician as a uterine dilator, in preference to sponge tents or other instrumental means, for the following reasons: 1. The hand is always available. 2. It can be easily governed. 3. Wherever a sponge tent or rubber bag can be inserted, the finger may be introduced. 4. The hand and the brain of the operator being in constant sympathy, giving him the precise idea of the condition of the parts, he is enabled to regulate the force necessary to effect dilatation. 5. Artificial dilators frequently require manual aid to keep them in place. 6. As the skilled surgeon, in the process of certain operations, finds greater safety in the use of the fingers than the knife, so may the obstetrician substitute his hand for artificial means as often as practicable.

In nine cases of convulsions, uterine hemorrhage, placenta prævia, vomiting, etc., in which this method was used, seven recovered and two proved fatal. The process of dilatation in a primipara, seven months advanced in pregnancy, is thus described:

The patient was chloroformed. The hand being oiled, a finger was passed into the orifice of the vagina, which was small; but after a short time it yielded to gentle pressure sufficiently to admit the whole hand. In the same manner the entrance into the os uteri was effected. Although the opening was so small as not to admit the point of the index-finger, the exertion of gentle force effected an entrance. Waiting until the cervix relaxed, another finger was then passed alongside the first, held until further relaxation ensued, when a third finger was insinuated, and so on until the five fingers, wedge-shaped, were all engaged within the cervical cavity. By gentle force, patiently sustained, the whole hand could now be passed into the cavity of the uterus, but it was allowed to remain in the cervical cavity until complete relaxation had taken place. This important point should be borne in mind, for on it greatly depends the success of the operation. The child was turned and extracted, and is now living. An hour and a half was occupied in the process, with no evidence that the soft parts had suffered contusion. The only uterine contraction observed was while the hand was in the womb; and deep anæsthesia was required to overcome it.

SURGICAL TREATMENT OF CAVITIES IN THE LUNGS.—The Berlin correspondent of the *Irish Hospital Gazette* (February 1, 1875) has, in conjunction with Dr. Koch, made a number of experiments on the effects of the injection of a strong solution of iodine into phthisically diseased lungs. The solution used was one part iodine and one part iodide of potassium to twenty parts of water. In no case was the operation followed by any unpleasant reaction; in quite a number of cases the temperature, which before the operation was that of hectic fever, sank immediately afterwards to normal, and remained there for several days. None of the patients complained of any subsequent pain, but in no

case was the phthisical tendency arrested. The disease seemed to run its ordinary course, and whenever a post-mortem examination was made the affected lung-tissue showed the evidence of having been influenced by the injection.

STERILITY AFTER LITHOTOMY.—Mr. W. T. Teevan has published (*Trans. Clinical Society*, vol. vii. pp. 179, 180; and *Trans. Path. Society*, vol. xvii. p. 186) four cases of this in males operated on by the lateral operation for stone. The stones removed from the bladders do not appear to have been large, and the subjects of operation were all young, two being infants. Mr. Teevan explains it by the operation, as usually performed, involving a laceration of the floor of the prostatic urethra, the ejaculatory ducts being torn across, or the orifices plugged with inflammatory exudation in the process of healing.—*Student's Journal*.

NOTES AND QUERIES.

LOUISVILLE, WINSTON COUNTY, MISS., February 26, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

MR. EDITOR,—I see in a number of your journal (Feb. 20) an article headed "Sulphate of Quinine in Premature Labor," by Harvey L. Byrd, M.D., etc., etc. I think the doctor could with equal propriety have headed the article "The Use of Purgatives in Premature Labor." In the summer of 1832, after attending one course of lectures in Transylvania University I attended a lady who had miscarried several times at about the third month. I gave her pills of rhubarb and aloes so as to keep her bowels gently open; she kept up all the time, did her house-work, and went her full time, had an easy labor, and a healthy child. I think the doctor's pills much better than my pill was, which may have had some soda in it, but not certain. The bromide of potassium and chloral was, I presume, a good auxiliary, but she might have done quite as well without quinia.

Yours, etc.,

E. FOSTER.

At a special meeting of the College of Physicians of Philadelphia, held Saturday, March 6, 1875, the following resolutions were unanimously adopted:

Resolved, That the Fellows of the College of Physicians have, with sincere sorrow and unusual emotion, heard of the death of Dr. George W. Norris, the Vice-President of the College, which occurred on March 4, after a long and painful illness.

Resolved, That, while submitting with reverence to the decree of Providence depriving them of one of their most esteemed associates, they cherish the consolation that regret for the loss sustained in his decease is accompanied by imperishable recollections of his personal worth.

Resolved, That the Fellows of the College have been deeply impressed by the courteous and gentle bearing of their late Vice-President, by his honorable conduct and high tone in his relations with his associates, by his studious avoidance of everything incompatible with the dignity of the profession of medicine, and by his entire freedom from all invidious personal assertion, while fully appreciative of the obligations of duty.

Resolved, That they regard his life and professional career as models worthy of imitation, and as eminently illustrative of the principles which have animated the conduct of the great and the good men of our profession.

Resolved, That his memory will be ever venerated for his whole-souled devotion to the interests of the profession, for his faithful maintenance of them, and for his life-long endeavor to promote the advancement and efficiency of that profession by his personal contributions.

Resolved, That the Secretary be instructed to transmit a copy of these resolutions to the family of Dr. Norris, and that they be published in the medical periodicals of this city.

JOHN H. PACKARD,
Secretary.

MEMORANDUM.

No changes of stations, etc., of officers of the Medical Department, U.S. Army, for the week ending Monday, February 8, 1875.

SATURDAY, MARCH 20, 1875.

ORIGINAL COMMUNICATIONS.

THE MANAGEMENT OF HEAD-LAST LABORS.

Read before the Philadelphia County Medical Society, January 13, 1875.

BY WILLAM GOODELL, M.D.,

Clinical Professor of the Diseases of Women and Children in the Hospital of the University of Pennsylvania, President of the Philadelphia County Medical Society, etc.

LABORS in which the head is born last are the bugbears of the physician; and well they may be, for Atropos, and not Lucina, presides over them. The tediousness of the labor, the probable ascent and possible fracture of the arms, the impaction of the head, the peril in which the child's life is placed, and the very disagreeable chance of breaking the neck, or, indeed, of leaving the head behind, present in their aggregate a very unwelcome group of complications. The chief dread of the physician is, however, the death of the child, and the length of the labor.

The causes of foetal death in this form of labor are manifold. But, what is worse, they accumulate in proportion as labor advances, and in the end act in concert. The first, in regard to time, comes from the irregularity of the presenting part, and consists in the escape of all the liquor amnii as soon as the bag of water breaks. The next is the delay attending the expulsive stage. The other causes lie in ambush until the breech is born, and then combine with the former in making a deadly assault upon the child's life. These include the compression of the cord and placenta, the partial detachment of the latter, the embarrassment to the uteroplacental circulation from the lessened size of the womb, and, finally, what is not uncommon, the long pauses between the pains. But there is yet another danger, not so generally known, which is, perhaps, the most common cause of death before delivery, and of feeble vitality or of death after delivery. When the placental circulation begins to flag, the child, unless at once delivered, keenly craves oxygen. Urged on by this air-hunger, it makes premature respiratory movements. But, since air cannot gain access to its nostrils, the child draws into its lungs the bloody and mucous discharges of the maternal passages. These foreign bodies so plug up the bronchia that the child is very liable to die either at once, from asphyxia, or within a few days after birth, from lobular pneumonia,—viz., atelectasis pulmonum.

From these causes the foetal mortality in head-last labors is large; so large as to be an opprobrium to the profession. From the statistics of fourteen of the most skilful of British obstetricians, Churchill shows that they lost very nearly one child in every three. In ordinary breech-cases Hodge rates the average of still-births at thirty-three per cent. According to MM. Capuron and Cazeaux, in the more difficult cases from sixty-six to seventy-five

per cent. perish. Said the late George T. Elliot (*Obstetric Clinic*, p. 347), "I always regret to meet a pelvic presentation in my practice, for fear that the child may not be born alive." In more or less vivid language, the testimony of this very distinguished obstetrician is sustained by all the authors of our text-books. Since, now, these statistics represent the experience of the most skilled specialists, of eminent teachers, of men who, by a large private and hospital practice, reached an unrivalled dexterity in their branch of the profession, it stands to reason that in the practice of the profession at large the average number of head-last still-births must be very much higher. For this mortality fifty per cent. is, I think, a very low estimate. But, mind, in the above statistics no account whatever has been taken of post-partum deaths from enfeebled vitality, or atelectasis pulmonum, so common in the infant after this kind of labor. This loss in itself is so large that it must not be overlooked. Since, therefore, pelvic presentations occur about once in every fifty cases of labor, it follows that in every thousand labors a practitioner attends he will, from this cause alone, meet with at least ten still-births and several deaths within a few days after birth.

In view of these facts, the objects of this paper will be to search out the best means for shortening the duration of this kind of labor, for preventing the death of the child, and, as a conjoint consequence, for giving the physician a greater confidence at the bedside of his patient. These ends can, in my opinion, be best attained by classifying pelvic presentations under the head of preternatural labors. For, since a name misleads, if we include them under natural labors, as is customary, we shall be less likely to render the often-needed help.

For shortening the first stage of head-last labors I have found nothing equal to the hydrate of chloral. Given every half-hour in doses of from ten to fifteen grains it promptly relaxes the most rigid cervix. In head-first labors the early rupture of the membranes usually hastens on the process of dilatation; but in head-last labors this means should never be employed. For obvious reasons it is of vital importance to keep the membranes intact until the os is fully and wholly open. If after the completion of the first stage of labor there is much delay in the descent of the breech, no better directions can be observed than those given by Barnes. The chest, shoulders, arms, legs, and sometimes the head of the child, all act conjointly in forming the base of a wedge, whose apex is represented by the breech. The apex engages, but the base, being more bulky than the brim or the lower segment of the womb, forbids further descent. By bringing down one leg, and preferably the one nearer to the pubic arch, this wedge is broken up, and the further progress of the labor placed under the control of the physician. He should, however, make no further traction on this leg unless it is loudly called for, and then only during a pain, lest the arms should become extended. From a pretty large experience, I can confidently recommend

this operation in all cases attended with delay. Nor should it be for a moment postponed after the heart-beats of the child become feeble. When the breech has descended so low as to preclude a resort to this operation, then, of course, the canonical methods of traction on the groins may be employed. But I really cannot understand why the gentle use of the forceps on the pelvis of the child is deemed more hurtful than that of the blunt hook in its groin. The pain that delivers the breech should be supplemented by traction or by supra-pubic propulsion, so that the arms and shoulders may also, if possible, be expelled at the same time. A loop of the cord must then be drawn down, so that its spirally-coiled vessels may not be constricted by being straightened out.

The breech being born, the uterine and abdominal muscles are in a great measure shorn of their expulsive power, and that at a time when most needed. The life of the child being now imperilled, its rescue is the next important consideration. From the mode of its death,—viz., from asphyxia,—it is plain that a prompt delivery is the only life-saving factor. Delay here means death. One of five minutes' time may be one minute too much. Hence there must be no waiting for the manifestation of such danger-signals as feeble pulsations in the cord, or convulsive jerks of the limbs; no loitering for a pain to begin, for the arms to come down, or for the head to become moulded. The proverb *quieta non movere* has here no application whatever. The physician should urge the woman to bear down; but if these efforts prove unavailing, he must hasten to bring down the arms, and at once proceed to the forcible extraction of the child. I say this advisedly, for, although our text-books teach otherwise, I am sure that in nine-tenths of breech-labors it is inaction and not traction that kills the child. Fettered by sentimental conservatism, or by an allegiance to traditional technics, the physician folds his arms, when, had he as many hands as a Hindoo deity, they should all be nimbly at work. Never shall I cease to regret my first breech-case of labor, in which, fearful of breaking the canons of obstetrics, and the child's neck as well, I let the only child its mother ever bore die before my eyes. So needful to the welfare of the child do I deem its speedy delivery to be, that were an arm so impacted as not to be safely released without a probably fatal delay, I should not hesitate to break it, or, at least, to run the risk of breaking it. Nor do I stand alone in advocating this heroic treatment. It is upheld by such excellent authorities as Braun* and Schroeder.† In such emergencies, however, as M'Clintock‡ and Bouchut§ have pointed out, and as I can bear witness, it is usually the clavicle that snaps, and not the humerus. In those rarer cases in which the humerus is broken, the fracture is often partial,—viz., of the green-stick kind. By the aid of thin pasteboard splints and of straps of adhesive

plaster, such injuries heal so readily and with so little deformity that they should weigh as trifles when life is at stake. In cases of pelves known to be ample, I can conceive of its being perfectly justifiable to follow Giffard's|| and Froriep's¶ plan of dragging the head through with the impacted arm extended above, rather than that of losing golden minutes in liberating it.

Supposing, then, that the trunk and arms are born, and the head, gripped by the brim, alone remains for extraction, is the forceps to be resorted to? I answer, "No;" for, although this instrument is handy enough when the head is at or near the outlet, in high operations its application is attended with so many difficulties that too much precious time is lost. The problem being to get the child's head out as soon as possible, the only factors for its solution are limited to supra-pubic pressure upon the head, and to traction on the body. But the former is not by itself trustworthy; while, as to the latter, the great majority of physicians labor under the idea that the neck of an infant cannot bear much traction. "Would you be willing," they triumphantly ask, "to lift up by its head an infant just dressed and lying in the nurse's lap?" "Would you," it may be retorted, "be willing to make as much traction upon the lower jaw of a newborn child as you have just made in flexing its head? or would you compress its head with the forceps as viciously as you did a few minutes ago?" For obvious reasons, I object very decidedly to the nursery game of lifting a child by its ears to make it "see London." But, were one of my children drowning, I should not hesitate to grapple for its naked body with a boat-hook, or to pull it out of the water by the hair, by the ear, by the nose, or by any prehensile portion of its body, regardless of any local injury it might sustain. Nay, were its limbs, like those of canny James Lambert (Charles Reade's aquatic hero), weighted down by the death-grips of some twenty other drowning persons, I should run the risk of breaking its neck in my frantic efforts to raise its chin above water-level. Now, a child presenting by the breech is in precisely this plight. It is under water, weighted down by the grip of the bony canal; it is drowning; and to any one drowning help must be sped,—help at all hazards.

The ancient Romans recognized this danger, and, as I believe, applied the only remedy for it. According to Pliny (*Historia Naturalis*, lib. vii. cap. viii.), they called all persons born in this manner, Agrippas. This name still puzzles etymologists; Aulus Gellius and Pliny himself derive it from *aggre partus*,—viz., *born with difficulty*,—but this is stoutly contested by others. With diffidence, I would suggest it to be either a derivative from *arripio*,—to snatch away; to take by force,—or a compound from the Greek word ἰρύψω,—a griffin, or fabled winged monster with four sets of talons,—from which our own word *grip* is derived. Thus interpreted, the name Agrippa is descriptive of the mode

¶ Journal Général, vol. xxiii. p. 460.

of birth, and means one snatched away, or taken away by force. But such a mode of delivery necessarily hinges on the tensile strength of an infant's neck, and this will, therefore, next engage our attention.

The adult neck is strong enough to bear the immense strain of the gallows-drop without sustaining a luxation of the atlas on the axis. Criminals executed in this manner usually die from suffocation. What holds good with adults holds good relatively with children; and it is wonderful what a strain their necks will safely bear. From experiments made adversely to version in narrow pelves, and, therefore, the less likely to overrate the tensile strength of the foetal neck, Matthews Duncan concludes (*British Medical Journal*, December 19, 1874, p. 763) that the neck of a dead child can, at term, sustain the average weight of one hundred and five pounds before the spinal column gives way, and one of one hundred and twenty pounds before the body parts from the head. These averages are, I think, under-estimated rather than over-estimated, for out of the four foetuses experimented upon, two of them weighed under six pounds; and the other two, weighing, respectively, seven pounds and seven ounces and eight pounds and fifteen ounces, sustained each weights of one hundred and forty-one pounds and one hundred and thirty-six pounds before decapitation took place.

In a difficult breech-case to which Joulin was called in long after the child was dead, he delivered the woman, after employing for twenty minutes a steady traction-force of one hundred and two pounds, made by a noose thrown around the neck of the child (*Traité complet d'Accouchements*, p. 1062). In conducting a series of experiments to determine the value of version in narrow pelves, he delivered with unbroken necks (p. 1050) the heads of three dead infants after putting on their feet a steady force, respectively, of one hundred and twenty-five, one hundred and forty-five, and one hundred and forty-eight pounds. But it must not be forgotten that these experiments were made upon dead children, and that the tensile strength of a living child's neck is presumptively greater. Again, Joulin also proved with his dynamometer that, without any purchase for the feet, and by pulling merely with the muscles of the arms, a robust man can exert on the forceps a maximum weight of one hundred and thirteen pounds. From analogous experiments made by Delore, a force of only one hundred pounds was reached (p. 1065).

Now, with the woman lying on her back and myself standing in a stooping posture before her, I have repeatedly delivered living and lusty children by putting on their necks all of my weight possible in that position. By grasping a cane in an analogous manner, and forcing it down on Fairbanks's scales, I find that one can for thirty seconds exert a steady downward pressure of about ten pounds more than half the weight of one's body. That is to say, I, who weigh one hundred and ninety pounds, can, for a very short time, exert a steady power of one hundred and five pounds. By throwing my weight suddenly upon the cane in quick jerks, I find that

I can tip the beam at one hundred and thirty pounds; and this great weight I certainly have on several occasions thrown on infants' necks. Yet I can confidently say that, notwithstanding this severe strain upon the spinal column, I have broken it but once, and have never failed to save the child whenever its birth was completed soon enough. Should much disproportion exist between the size of the head and the capacity of the brim, it is emphatically a case of "neck or nothing;" and the operator must not shrink from promptly using very great force,—a force, indeed, only just short of detraction. But I do not believe it possible for a physician even to break the neck of a mature child, much less to behead it, if he applies a steady traction-force in the manner above described,—viz., by pushing the neck and body of the child backward and downward, just as he makes downward pressure on the lock of the forceps. Not even when the infant is immature should the efforts of the physician be hampered by the fear of sudden decoliation. For the spinal column always yields before the skin and muscles part, and the consequent jerk and the immediate elongation of the neck will give timely warning when to use less force, or, the child being now dead, to end the labor by craniotomy or cephalotripsy. Far better is it, in these emergencies, to kill in attempting to save than to kill by cowardly inaction.

I once saw the strength of the child's neck put to a crucial test, and the result amazed me. I frankly confess that had I not been an eye-witness I should have been a doubter. It was a case of a primipara with a flat pelvis and a large but putrid foetus. After craniotomy had been performed, a further obstruction to delivery lay in the bloated chest and belly. Before this second complication was recognized, each one of the four physicians present, including myself, took his turn at the forceps. From a natural rivalry, the traction thus necessarily made upon the neck of the foetus by three of us in succession was no child's play. But that made by the fourth gentleman, a distinguished member of this Society, exhibited so much power and originality that I shall here describe it. He turned the woman over on her side, brought her hips to the edge of the bed, and applied Hodge's forceps. He next carefully tucked a sheet around the lock of the instrument, removed his shoes, sat in a chair, and placed one foot across the perineum, the other across the vulva. He then grasped the handles, straightened out his body, and pulled with all his might and main, making every muscle in his body quiver with the effort. Yet, in spite of the enormous strain brought to bear upon the neck of the child, it was simply lengthened out, but not broken. The cranial stump was brought down to the outlet, but it literally sprang back at every intermission of the traction. This behavior of the head, or rather of what was left of it, was in fact the first clue that led to the discovery of the obstructive size of the child's body.

Although these facts show the wonderful tensile strength of the foetal neck, yet, in order to extract the head with a minimum of traction-force, it is of

great importance to exert the power to the best mechanical advantage, and to grade it to the resistance. This brings me to the mode of making traction; but in order to understand the subject fully it will be first necessary to study the configuration of the foetal head, and the mechanism of its extraction. In so far as breech-labors are concerned, the foetal head is made up of the frustums of two cones meeting in one common base. One cone is that portion of the head behind the biparietal circumference; the other consists of that portion in front of the same plane. I shall distinguish them by the names of the "fore cone" and the "hind cone." Looking from below upwards,—viz., from the base to the vault,—the head is also wedge-shaped. This I shall call the "wedge." Now, it has been found over and over again, except in those rare cases of uniformly contracted pelves, that, when an infant is pulled through the brim by the feet, the shorter diameter of the fore cone—viz., the bitemporal diameter—tends to pass directly between the sacral promontory and the pubic symphysis, and the hind cone, together with the large biparietal diameter,—viz., the base common to both cones,—to pass to one or the other side of these two osseous points. The shorter the conjugate diameter the more inflexible is this law. The head thus makes its first movement of descent in an unflexed condition, but there is usually plenty of room in the bisiliac diameter for the occipito-frontal diameter to pass. Again, the distance measured from the chin to the nipped points of the head—viz., the ends of the bitemporal diameter—being less than the distance from the occipital protuberance to the same points, the chin can hardly ever catch over the iliac edges of the brim. Theoretically, the extension of the head by the arrest of the chin over any point of the brim is a possible accident, but practically its occurrence is so rare that it may be left out of consideration. Mauriceau saw but one case; in many thousand labors Madame Lachapelle did not meet with one; nor did Velpeau, who, however, notes one occurring in the practice of Leroux, and another in that of Eckardt. Joulin states (p. 559) that he not only never met with this complication, but that he in vain repeatedly tried to bring it about by forcing the back of the child into the hollow of the sacrum. The cause of this almost invariable adjustment of the occipito-frontal diameter to the transverse diameter of the pelvis is the round and hard surface of the occiput, which glides off to one side of the sloping promontory. The head, therefore, passes the brim in the transverse position and in an unflexed condition. But when it is brought into relation with new pelvic diameters, the greater friction of the broader and harder surface of the hind cone brings about the movements of flexion and rotation.

Granting these premises, it follows that the occipital protuberance is far more likely than the chin to hook over the edge of the brim, and that flexion is an undesirable movement while the head is passing through the conjugate. The rule, therefore, to make flexion at this stage of labor, by passing two fingers into the mouth or on each side of the

nose, is not only a piece of meddlesome midwifery, but it entails the loss of much traction-power, and is a sheer waste of very precious time.

According as the pelvis is of average size or is narrowed in its conjugate diameter, I adopt two modes of extracting the wedge-shaped head; but the one that I shall first describe is the one that I invariably first employ. The woman may retain the lateral position, but, for reasons to be hereafter given, I much prefer her to lie on her back, with her hips brought to the edge of the bed. In a brim narrowed in its conjugate, the promontory is usually sharp and projecting. The sacral side of the after-coming head tends, therefore, to be bent in by this osseous point and to become fixed by it. Hence the extrication of the head as a whole can take place only when its pubic side revolves around the promontory and glides down over the smooth under surface of the pubic symphysis. Bearing this fact in mind, it is important that the sacral side of the head should become fixed at a point as high up as possible,—viz., as near to its vault as possible. To gain this end, the physician, after grasping the nape of the neck with one hand, and the ankles with the other, should make his first movement of traction in the axis of the outlet, for then the pubic side of the head will be tilted away from the inlet, while the sacral side will proportionately descend over the edge of the promontory, and affront the brim. This canting of the head can be very materially aided by an intelligent assistant, who will make very firm backward and downward pressure with both hands, through the now flaccid abdominal wall, upon the vault of the head. By this manœuvre the promontory is made to indent the sacral side of the head at a point still higher up, and nearer to the vault; hence the arm of the lever, measured by a line drawn from the base of the skull to this fixed point, will be correspondingly lengthened,—a mechanical advantage not to be overlooked. If now, *without for a moment relaxing, but rather increasing, the original traction-force*, its direction be reversed, and the body of the child be swept backwards upon the coccyx, the neck being also forced downward and backward into the hollow of the sacrum, the sacral side of the child's head becomes deeply bent in, and the pubic side is made to revolve around the promontory and descend with the least expenditure of traction-force. In other words, the head is warped around the promontory. Should the neck be so short, or the pelvis so deep, that the physician cannot well grasp the nape, he may loop a thin muslin sling over it, and draw on the ends, which should meet in front of the chest.

Whenever this mode of traction fails to release the head from the grip of the brim, or the difficulty lies rather in the size of the head than in the narrowness of the pelvis, I have, on several occasions, succeeded by a pump-handle movement. Made with a steady and an unremitting traction, it will cause each side of the wedge-shaped head to descend alternately. The range of oscillation should extend from the axis of the outlet anteriorly, to very firm pressure on the coccyx posteriorly. With a sharply-defined promontory this up-and-down movement

does not ordinarily succeed, unless the parietal bone has been broken in or greatly depressed as a whole, and not simply indented. Otherwise, the sacral side of the head is held fast, and the pubic side will then librate around the indented, and therefore fixed, point, merely rising and falling, without any onward progress whatever. But in the breech-cases ordinarily met with, in which the sacro-vertebral angle is usually round and knobby, or in those of large heads and average pelves, this pump-handle movement will be found a very precious expedient.

To either method supra-pubic propulsion by the hands of an assistant is a very important adjuvant. It can with safety be made to any extent, and will greatly lessen the amount of traction-force necessary for delivery. As soon as the head has passed the brim, which it does usually with a distinct jerk, flexion and rotation spontaneously take place, and the line of traction must then be changed to that of the outlet. When finally the head is about to clear the bony canal, the body of the child should be raised up in front of the pubes, according to Hodge's plan, and traction made directly upward in a line at a right angle to the mother's body. This final method of traction augments the flexion of the head, and obviates the necessity for putting two fingers into the child's mouth. When the face presses on the soft parts, two fingers passed up into the rectum will still further increase the flexion of the head, and will serve to protect the perineum from injury.

To sum up, then,—the mechanism of a forced delivery consists in propulsion and three movements of unremitting traction. That failing, in propulsion and a pump-handle movement of traction. Of the three movements of traction, the first is made in the axis of the outlet, the second in the axis of the inlet, and the third in the curve of the obstetric canal.

I have been somewhat minute in these directions, because physicians, by continuing the backward traction long after the head has slipped past the brim, sometimes fail to deliver, and because by this faulty traction the chin hooks over the perineum and badly tears it. One word with regard to the perineum: In head-first labors due time can generally be given for its complete dilatation; but in head-last labors even seconds are too precious to be thus wasted. If, therefore, air cannot be communicated to the mouth or to the nostrils of the child through the gutter made by the physician's fingers, he must disregard the consequences to the mother and forcibly deliver by traction, or, this failing, by the forceps. Should the perineum be torn, as it usually will be in a fat primipara, a perfect union of the wound may be confidently looked for from the immediate introduction of wire sutures.

In both the previously-given modes of extraction I prefer the woman to be on her back, with her hips brought slightly over the edge of the bedstead, and each knee supported by an assistant. My reasons for this position in preference to the lateral one are: that the propulsive pressure is then more efficiently given either by the hands of a third assistant, or by the free hands of the two assistants; that since the power thus applied resolves itself into a question

of weight and not of strength, very few physicians, while bending forward in front of the woman thus placed, can exert a steady force of one hundred pounds upon the neck of the child; and, finally, that the upper hand of the physician can then force the neck into the hollow of the sacrum and thus make the line of traction somewhat behind the axis of the superior strait.

In conclusion, let me say that, since adjusting all sentimental considerations for the child's neck to a sliding scale of pounds avoirdupois, and since adopting the foregoing methods of delivery, I approach a case of head-last labor with an assurance of success such as I never had before, and such as I wish to impart to those who lose heart the moment the examining finger discovers that the head is not the presenting part.

A CASE OF BASILAR MENINGITIS IN WHICH THE OPHTHALMOSCOPE APPEARANCES (CHOKED DISK) WERE OBSERVED ONE MONTH BEFORE DEATH.

WITH THE ACCOUNT OF THE POST-MORTEM EXAMINATION.

BY D. B. ST. JOHN ROOSA, M.D.,

Professor of Diseases of the Eye and Ear in the University of the City of New York.

THROUGH the courtesy of Dr. T. E. Satterthwaite, Curator of the Presbyterian Hospital, and Dr. James L. Banks, Attending Physician, I am enabled to report a case which derives its chief interest from the careful post-mortem examination of the brain that was made by Dr. S. On the 24th of November, 1874, I was asked to see a young girl in Cherry Street, who was said to be suffering from pain in the eyes and ears. I found an emaciated but tolerably strong girl of about fourteen years of age, sitting up, but complaining of headache and of occasional pains through her ears and eyes. Her hearing was good, and her mental powers were unimpaired. She could read the type of a book of rather coarse type, so that at a rough estimate, having no test type with me, I concluded that her vision was at least one-half, $\frac{2}{4}$, or perhaps even $\frac{3}{4}$. On examining the bottom of the eyes with the ophthalmoscope, I found the media perfectly clear, the choroid and retina sound, but the optic papilla swelled, the veins large and tortuous, and the arteries small. Both nerve-entrances were in the same condition. There was no intolerance of light. The appetite was impaired, and the general nutrition was also in a poor state. The patient had an occasional chill, and had been gradually getting into the present state for about a month. The drum-heads showed no morbid change.

My diagnosis, made in the presence of Mr. Kreekorian, student of medicine, was descending optic neuritis from basilar meningitis. She was placed upon bromide of potassium, quinine, beef-tea, milk, etc.

The patient was living in a very small room, surrounded by all the other members of the family, some five or six in number, and she was therefore

removed to the Presbyterian Hospital, where she died on the 20th of December, or about twenty-four days after I made the ophthalmoscopic examination. The general symptoms and course of her case after admission to the Hospital, as furnished me by the Attending Physician, Dr. James L. Banks, were as follows :

S. H., æt. 13; born in Syria; single; no occupation; father Armenian and mother Greek. Good family history; says she began to have severe paroxysms of headache and vomiting, which rapidly increased in frequency and intensity. During past month, according to the statement of her friends, she has had epileptiform convulsions, strabismus, and attacks of blindness. In spite of the administration of bromide of potassium, the convulsions have been more frequent and more severe of late.

On admission, patient is fairly nourished; slightly anæmic. Dark hair and eyes, and fair skin. Complains of very severe pain in head, chiefly in frontal region and in back of neck. Says that the pain is quite constant, but is much more severe at some times than at others. The light hurts her eyes, and blue glasses are worn as a protection. Says that sometimes her vision becomes very "dim;" at present it appears to be good. Pulse and temperature normal; skin and muscular system natural; pupils widely dilated, but responsive to light. Appetite very poor. Bowels costive. Patient feels able to be up and dressed during the day.

There was no special change in the condition of the patient until the 5th of December, when she had nine epileptiform convulsions during the morning, in quick succession, and slight spasms almost continuously during the afternoon and night. On the 6th she was quiet and partially unconscious, moaning and complaining of headache in frontal region. Occasionally strabismus was noticed. Bowels constipated. The following day, the 7th, she sat up and dressed, and said she felt much better, complaining of no pain. This continued until the 9th, when she had again great pain in head, and vomited frequently, but there was no convulsion until 12 P.M. of same day.

Morning of the 10th she was quiet, but unconscious.

On the 11th and 12th had frequent spasms, great pain in head and neck, and unconscious part of time. Paralysis of lower extremities then appeared, with incontinence of urine and fæces; pupils were unequally dilated.

No change in condition on 13th and 14th. On 15th, spasms less frequent; pulse is losing strength, and she is emaciating rapidly.

On the 16th, no spasms; complained of headache; began to refuse nourishment, having taken it well hitherto; pulse very weak. It was then observed that patient was blind, and partially deaf. She continued in this condition until her death, three days after.

The treatment consisted in the administration of bromide of potassium, five grains every four hours, increased to five grains every three hours, and combined with iod. pot., etc., etc.; blister (cantharides) to back of neck; ice-bag applied to head (also to spine, without good effect, and discontinued). Mag. sol. morph., \mathfrak{M} iv hypodermically, to control restlessness and spasm, was given twice. Bowels were moved by enema. Extra diet, milk, beef-tea, etc., etc., was ordered, and, although there was some apparent improvement at first under this treatment, the patient gradually lost strength, emaciating rapidly, and she died very quietly at 3 P.M. on the 19th of December.

Autopsy, made by Dr. Satterthwaite. Body greatly emaciated; the brain and upper portion of cord were

only parts removed. Meninges of brain and cord congested, and of bright-red color; dura mater studded with numerous small, yellowish-white points; over convexity of brain, strong adhesions at a few points between dura and pia mater; a faint opaque gelatinous deposit was seen in pia mater at some points. At the base there was a large area of softening, extending from pons Varolii to anterior border of optic commissure and from one middle cerebral lobe to the other, and reaching deep into substance of brain, on the right side extending to and embracing a portion of the inner wall of the right ventricle; superficially it had a gelatinous look, while internally it was more or less mottled with yellowish and red spots, and there were small portions of broken and plugged vessels seen in it; above the left optic tract was a small, soft, deep-red clot, about the size of a small hazel-nut, surrounded by a softened mass, and there was another smaller extravasation, not coagulated, above and opposite the right crus. In the interior of left lateral ventricle some of the softened material had a creamy look. Under the microscope, this material was found to be made up in part of lymphoid cells and red corpuscles, but chiefly of large exudation-cells and granular matter. Some of these collections of cells had undergone degeneration, so that they were only recognized by their outline. The ventricles were dilated, and contained fluid in large quantities. It was clear; but the floors of the ventricles to the posterior cornua were covered with a thin layer of coagulated blood. The vessels at the base and in the fissure of Sylvius were empty for the most part, and milary granulations about them could not be detected with certainty. The brain-substance was remarkably pale.

I am sorry that the post-mortem examination does not include an account of the condition of the optic nerves and eyeball; but Dr. Satterthwaite found it impracticable to make an examination except of the brain. Yet the results of this investigation, in connection with the clinical history and ophthalmoscopic examination, render the case, as it seems to me, an interesting contribution to the literature of descending neuritis optica.

NOTES OF HOSPITAL PRACTICE.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

SERVICE OF DR. LOUIS A. DUHRING.

Reported by ARTHUR VAN HARLINGEN, M.D.

SYCOSIS NON-PARASITICA.

THIS man presents an eruption on the right cheek, extending over an area of several square inches, involving, as you observe, not only the skin, but the follicles of the hair: it is, in fact, a case of sycosis. But there are two kinds of sycosis: one depending upon the presence of a vegetable fungus, and known as parasitic sycosis; the other a simple inflammation involving the hair-follicles, and known as non-parasitic sycosis. Which have we here? This is an important question, for our plan of treatment will be of one kind or another according to the diagnosis arrived at. Our patient tells us that the appearance of the affection has, since it first showed itself, become materially changed. At first the eruption was moist; now, on the contrary, it is dry, red, and scaly in most places, while a few pustules may be observed around the hair-follicles. Were this parasitic sycosis, the appearances presented would be quite different; great disfigurement would

exist, nodules and tubercles of various sizes, perhaps even as large as a cherry, would be observed under the skin, this form of disease going deeply into the tissues.

Our patient tells us that the eruption itches and burns severely at times; and this is another fact which would incline us to doubt its parasitic origin, for parasitic sycosis never gives rise to so great a degree of itching and burning as we have here.

We have here, then, a case of non-parasitic sycosis, the disease having commenced, probably, as an eczema, and having subsequently penetrated the hair-sacs and glands, giving rise to inflammation in these parts, and terminating in the condition we see before us.

The treatment of these cases is manifold: sometimes one remedy will answer the purpose; at another time this will fail, and we must have recourse to a different one. The first thing to do, invariably, however, is to have the patient's beard kept closely shaved. To this the patient will probably at first object, on account of the pain to which this operation gives rise; but after the first day or so it becomes much less painful, sometimes not at all so. Shaving is an absolute necessity in sycosis, both for the sake of cleanliness and because we cannot otherwise apply the local means necessary with any degree of thoroughness. The hairs, too, when allowed to grow, act as irritants. After having been cleanly shaved, our patient will have applied to all the affected parts of the skin the following ointment:

R Sulphuris loti, ʒss;
Adipis, ʒi.—M.

The diseased patch is to be carefully cleansed with castile soap and warm water, and, after drying, the ointment is to be thoroughly worked in with the finger. This procedure is to be repeated morning and evening.

As regards diagnosis, one word more may be said. In a certain number of cases this may be very difficult and obscure if we rely upon the naked-eye appearances alone. Fortunately, we have in the microscope an aid which will enable us to decide in every instance. The presence or absence of the characteristic fungus found in the epidermis and in the hair-shaft itself will decide the question without doubt.

TRANSLATIONS.

ON MICRO-ORGANISMS IN SUPPURATIONS—THEIR INFLUENCE UPON THE COURSE OF WOUNDS, AND THE MEANS OF OPPOSING THEIR DEVELOPMENT.—At a recent meeting of the Académie des Sciences, M. P. Bouloumie read a note upon this subject, from which we condense the following:

1. Pus from any collection not in direct or indirect connection with a wound never contains micro-organisms, with the exception of certain minute brilliantly refractive points often joined two and two. Pus from a wound, whatever its nature and whatever the dressing employed, has always afforded micro-organisms, usually endowed with movements which become more appreciable when the pus is diluted. In pus from an abscess in the vicinity of a wound, the number and variety of organic forms observed depend upon whether the abscess is in a tissue continuous with or only in contiguity to that in which the wound is situated. In the first case the forms are numerous and varied, in the latter few and simple.

The movements of these organisms, which are hardly perceptible at the moment the abscess is opened, become much more so after exposure of the pus to air, and especially if the latter is diluted. The elements observed in pus, besides the pus-globules, the white and the red blood-globules, are almost constantly the same; they are composed of mobile and immobile single

granules, chaplets of the same, etc., and are described at length by M. Bouloumie. All these elements are surrounded by an amorphous, fatty, granular substance escaped from the pus in process of destruction.

2. No dressing will absolutely prevent the presence of micro-organisms in wounds, although certain applications may modify their number and activity. Alcohol and glycerin appear to be the dressings which repress most powerfully the vitality and mobility of micro-organisms. Lister's dressings do not prevent their appearance in the products of suppuration.

Raw-cotton dressing, made with care, the wound having been cleansed with dilute alcohol and covered immediately with lint soaked in glycerin, permits the development of organisms only in such small quantities as to lead one to believe them contained in the dressing at the time of its application.

3. The micro-organisms above described do not exercise an equally morbid influence upon the wound under all circumstances, or upon the individual. They may exist in the products of suppuration without hindering cicatrization or injuring the patient's health. They may, however, at times invade the parts in the vicinity of a wound, and give rise to abscess in the neighborhood. They may, by means of the lymphatic or venous system, invade a healthy organism without doing anything more than provoking reaction and eliminative dejections. They may invade an organism already profoundly affected, and may develop septicæmia; first by their toxic action, then by the virulent action of the elements disorganized by them.

4. Among the agents used for dressings, it is necessary to choose those which exercise a favorable action upon cicatrization, and which, at the same time, are opposed to the vitality and proliferation of the micro-organisms. From this point of view, alcohol and glycerin ought to have the preference. They arrest the life of those vibrios which require water, by depriving them of their water of constitution.

5. It is by proper dressing, very often, that the first step in infection is prevented, and it is by an intelligent hygiene that the chances of generalization on the part of the morbidic ferments may be diminished, should they escape beyond the limits of the wound.—Abstract from *Bull. Gén. de Thérap.*, January 30, 1875. X.

PARALYSIS OF THE CERVICAL SYMPATHETIC.—According to Dr. Nicati (*L'Abeille Méd.*, No. 3, 1875; from *Archives Méd. Belges*), this affection is quite frequent, although it generally passes unnoticed on account of its usual innocence. A slight drooping of the eyelid, accompanied by contraction of the pupil as well as some coloration and perspiration of the face, is all that may be noticed.

What has been called hyperidrosis, lateral facial epidrosis, anidrosis, is nothing more than a paralysis of the sympathetic nerve. M. Nicati distinguishes three periods in paralysis of the sympathetic: 1, a period of *prodromata*, or artificial irritation, the symptoms of which are similar to those produced by artificial irritation of the cervical sympathetic in animals; of this period he gives, as an example, a case of exophthalmic goitre; 2, a *first period of paralysis*, of which the symptoms are those observed in animals after section of the cervical filaments: contraction of the pupil, injection of the vessels of the corresponding side of the head, augmentation of heat in the same parts and as far as the axilla, frequent sweats; 3, a *third period*, characterized by atrophy of the diseased parts, loss of flesh in the paralyzed localities, and want of perspiration in the same. All these various phenomena, which may show themselves singly or together in paralysis of the cervical sympathetic, have been studied with care, and are detailed at some length by Dr. Nicati in his communication. X.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MARCH 20, 1875.

EDITORIAL.

PHILANTHROPY RUN MAD.

THE active and virulent assaults in London upon vivisection and those who practise it have already been alluded to in these columns; but the cool impudence of a recent act of the Royal Society for the Protection of Animals seems to us to exceed anything that we have seen or read of for a long time. It must be remembered that this Society has already taken the ground that vivisection is criminal, and that all performers of it ought to be as vigorously prosecuted as those who starve or drive to death cattle or horses, or who in Hogarthian methods put to shame and suffering the smaller domestic animals. Having taken this position, the Society now sends a circular to all the medical societies, medical schools, hospitals, etc., of Great Britain, stating, "It has been alleged that experiments upon animals are practised under the care or patronage of these various schools, societies, etc.," and asking that "a committee of the Society for their protection may be present as mute spectators on the occasion alluded to when operations on living animals are appointed to be performed at your institution, in order that we may report the proceedings of them." We are sorry to have to state that some of the medical societies have returned respectful though negative answers to these petitions. It would have been better not to notice them.

London is not the only place where ultra, bigoted

philanthropists exist: we have the same class in this community. Long ago our own society in the female branch embarrassed vivisection in this city by preventing the use of the condemned dogs of the pound. Of course, by this senseless procedure they did not stop scientific investigations, but only made them more troublesome and expensive, and thereby really increased the probabilities of cruelty being practised: when a dog costs five dollars instead of fifty cents, there is evidently a constant temptation to make the single animal go as far as possible.

The moral of the famous answer of Sir Astley Cooper to the Committee of the House of Parliament, "If you do not allow us the bodies of convicts and paupers, we will take those of members of Parliament," is perfectly applicable to the present case. The reputed action of the chief of the Paris police in the case of Magendie was a much wiser one than that of our ladies of wealth. The story, as we have heard it, is that one of Magendie's dogs having escaped in a very severely wounded condition went home to his master, who happened to hold the office aforesaid. The next day every policeman was on the *qui vive* to discover who had dared to commit the dastardly outrage, and by-and-by the crime was traced to the luckless vivisector. He, however, so explained the matter to the chief of the police, and was so successful in undoing what he had done, that not only was the dog restored to health, but his master was converted into an ally, so that ever afterwards the city pound was open to Magendie.

Scientific investigation has continued to go on in the face of papal bulls and religious persecution unto the shedding of blood; much less shall it be stopped by any band of sentimental philanthropists, who bear to the real lover of his kind about the same relation that an old childless woman hugging her lap-dog does to the mother with the babe in her arms.

The less of useful work any one has to do in the world, the more time is left for making trouble; and the false assertions of Mr. Bergh and his kindred may in this country—where public opinion is so powerful—make a great deal of trouble, if we do not take care to put the real facts of the case before the people. It has been with great pleasure, therefore, that we have recently read very just editorials and articles upon the subject in the *Nation* and other of our leading popular journals and papers. Much, of course, can be done in the way of influencing public opinion by means of the press; but even more can be accomplished by every physician making, by personal efforts, the little circle that looks up to him understand the merits of the case. The

little brochure of Prof. Dalton* is an excellent one to loan to friends and patients; but the following condensed statement from the *British Medical Journal* will be perhaps more useful for the refreshment of the memory of the physician himself.

WHAT HAS VIVISECTION DONE FOR MEDICAL SCIENCE?

A. *It has succeeded in advancing our Knowledge of Physiology, by—*

1. Discovery of the two classes of nerves, sensory and motor, by Sir Charles Bell.
2. Discovery of the functions (motor) of the *portio dura* of the seventh pair, by Sir Charles Bell. Previously to this discovery, the *portio dura* was often cut by surgeons for the cure of neuralgia!
3. Discovery of the functions of the anterior and posterior roots of the spinal nerves, by Sir Charles Bell.
4. Discovery of the functions of the anterior and posterior columns of the spinal cord, by Brown-Séguard and others.
5. Discovery of one of the functions of the cerebellum in co-ordinating muscular movements, by Flourens and others.
6. Discovery of the functions of the gray matter on the surface of the cerebral hemispheres as connected with sensation and volition, by Flourens, Magendie, etc.
7. Discovery of the motor functions of the gray matter covering certain convolutions in the anterior part of the cerebral hemispheres, by Hitzig, Fritch, Ferrier, Gudden, and Nothnagel.
8. Demonstration of the circulation of the blood, by Harvey.
9. Measurement of the static force of the heart, and discovery of other hydraulic phenomena of the circulation, by Stephen Hales, Ludwig, etc.
10. Discovery that atmospheric air is necessary to the maintenance of life, and that, when stupefied by its withdrawal, animals may be resuscitated by readmitting it, by Robert Boyle, in 1670.
11. Discovery that atmospheric air by continued breathing becomes vitiated and unfit for respiration, by Boyle.
12. Discovery that the air was not only vitiated but also diminished in volume by the respiration of animals, by Mayou, in 1674.
13. Discovery of the relation, as regards respiration, between animal and vegetable life, by Priestley, in 1722.
14. Great discoveries by Lavoisier on the physiology of respiration, from 1775 to 1780; namely, that respiration acts only on the respirable portion of the air, or oxygen, while the remainder, nitrogen, is entirely passive in the process; secondly, that when animals are confined in a limited space, they die when they have absorbed, or converted into carbonic acid, the greater part of the oxygen, and so reduced the air to the state of an irrespirable gas.

15. Numerous facts in the physiology of digestion, observed by Blondlot, Schwann, Bernard, Lehmann, and others, by experiments on animals.

16. The discovery of the functions of the lacteals, by Colin, Bernard, Ludwig, and others.

17. The discovery of the functions of the eighth pair of nerves in relation to deglutition, phonation, respiration, and cardiac action, by John Reid and others.

18. The discovery of the functions of the sympathetic system of nerves, by Pourfour du Petit, in 1727, Dupuy, in 1816, Brachet, in 1837, John Reid, and Brown-Séguard.

19. The discovery of the phenomena of diastaltic or reflex action, by Marshall Hall.

20. The discovery of the action of light on the retina, by Homgren, Dewar, and McKendrick.

21. The discovery of the glycogenic function of the liver, by Bernard, Macdonnell, Pavy, etc.

22. The discoveries of the whole series of facts in the domain of electro-physiology, by Matteucci, Du Bois-Reymond, Pflüger, and many others. These discoveries have important practical bearings.

B. *In aiding Medicine and Surgery.*

1. The transfusion of blood, and introduction directly into blood of medicines; first proposed by Robert Boyle, in 1665. In 1665 Lower transfused blood from vessels of one animal into those of another. First done in human being by Dennis and Emmerets, in France, in 1666. Blundell's celebrated experiments on animals in 1818. Since done by many others,—Dumas, Milne-Edwards, Dieffenbach, Bischoff, Doubleday, Brigham, Waller, Burton Brown, Klett, Lane, Levy, Bérard, etc.

2. Artificial respiration. Vesalius showed that by blowing up the lungs with air, after the chest was opened, stoppage of the heart's action might be delayed for some time. Hook, in 1664, first demonstrated the possibility of artificial respiration. Brodie, Hope, Le Gallois, Wilson Philip, Marshall Hall, and Silvester have practised it on human beings.

3. The causes of the cardiac sounds have been determined entirely by vivisectional experiments.

4. Phenomena of the circulation within the cranium examined experimentally by Kelly, Burrows, Reid, etc.

5. Hunter's operation for aneurism was first demonstrated and tried on living animals. This he did in 1785. He also found, by experiments on animals, that in many cases the arterial coats were diseased immediately above the aneurism, and that consequently it was necessary, in order to avoid secondary hemorrhage, to place the ligature higher up.

6. The office of the periosteum in regeneration of bone has been demonstrated experimentally by Du Hamel in 1740, Hunter in 1772, Syme in 1837, Wagner in 1853, and Leopold Ollier in 1858. The practical importance of these observations is recognized by all surgeons who have had much to do with the diseases of bones and joints.

7. The researches of Redfern into disease of cartilage.

* Experimentation on Animals. New York, F. W. Christern, 1875.

8. The researches of Stricker, Cohnheim, Von Recklinghausen, and many others, on inflammation, more especially of cornea and serous membranes.

9. Without vivisection experiments, we would know very little of the phenomena of inflammation.

10. Experimental inquiries into many zymotic diseases showing occurrence of micrococci.

C. In advancing Therapeutics, Relief of Pain, etc.

1. Use of ether.

2. Use of chloroform.

3. Chloral discovered experimentally by Liebreich.

4. The actions of all remedies are only definitely ascertained by experiments on animals.

5. Action of Calabar bean, by Fraser.

6. Antagonism between active substances and the study of antidotes,—many observers.

The above are simply examples which have readily occurred to the mind. To record all the facts given to physiology by experiments on animals would simply be to write the history of the science. Therapeutics is yet in its infancy; but nearly all the facts definitely known regarding the actions of remedies have been gained by experiments on animals. To stop experiments on animals would as surely arrest the progress of physiology, pathology, and therapeutics, as an edict preventing the chemist from the use of the retort, test-tube, acids, and alkalies, would arrest the progress of chemistry.

CORRESPONDENCE.

BALTIMORE, March 2, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—For once, Baltimore has a genuine sensation, and the medical profession, as well as upper and lower Ten-dom, is making the most of it. On Tuesday, February 16, Dr. Dausch, assisted by Dr. Mansfield, delivered Mrs. Hahn, 119 Low Street, of four daughters. The first child presented by the right shoulder, the other three were footlings. There were two placentæ, three children being attached to one, and one having its own independent supply. The large placenta was about fifteen inches in diameter, and on the foetal surface had the appearance of three ordinary placentæ, with a cord in the centre of each, placed so as to form a circle, thus, , but the maternal surface showed no marks of division, and they could not be separated without laceration. The labor occupied about an hour and a half, and was free from pain. Ergot was given in 3ij doses, but produced no contractions of the uterus.

The mother is small, and in an advanced stage of consumption. This was her third confinement, and both her other children were breech-presentations, and the labor free from pain. The quartet weigh about twenty-four pounds, and the placentæ about four pounds,

which gives about thirty pounds as the weight of the uterine contents before delivery. The children are strong and healthy, and the father is doing a good business exhibiting them to the curious, for which he charges an admission-fee. Collections have been made at the hotels and other places for the benefit of this interesting family. It is intimated that a cow would be a very acceptable present.

In remarks on this case at the Medical and Surgical Society, Dr. Morris said that, according to his experience, abnormal presentations did not have the usual phenomena of labor. There is generally a state of quietude; contractions cannot be aroused, and the os dilates unheeded.

At the same meeting of the Society, Dr. Cathell advocated the external application of fluid extract of belladonna to the throat of patients with *scarlatina*. He had used it for eight years, and had never had a case where it was used in which the glands became excessively swollen. It seems to keep the glands in a quiescent state, so that they show no sympathy with the disease. It does not lessen the proportional mortality, and will not reduce the swelling of glands already inflamed. He thought it would be useful in bubo and all local inflammation of glands.

Dr. Lynch thought it important if belladonna will prevent induration or promote resolution of glands; but *scarlatina*-patients die from the fever-heat or from the intensity of the poison; and frequently the glands do not become involved. The involvement of the glands does not affect the mortality.

Dr. Cathell thought the enlargement of the glands, with the subsequent inflammation and sloughing, might add much to the danger. Prof. Lynch said he had never seen a case in which the danger was so increased.

Dr. Morris said the application of belladonna to swellings was as old as the use of the drug. He has used it for enlarged ovaries, but it is doubtful whether it does good. The mere swelling of the glands is not very alarming or significant, but if it will prevent supuration it is something gained.

Dr. Friedenwald had used it for years, in combination with camphor, in *scarlatina*. It seemed beneficial.

Dr. Noel asked what was the value of notched teeth, as described by Hutchinson, as an evidence of syphilis. He has a child under his care whose teeth are notched, and it has nervous symptoms which seem to indicate a tumor of the brain.

Dr. Friedenwald thought the test of very doubtful character, as he had seen such teeth in perfectly healthy children, and it is frequently seen in some forms of interstitial keratitis.

Dr. J. N. Monmonier spoke of the beneficial effects of inhalation in chronic diseases of the larynx and trachea.

Dr. Caldwell said that he had seen very beneficial effects in whooping-cough from the inhalation of belladonna and potass. brom.

At the Baltimore Medical Association, Dr. Chew read an interesting paper on the sounds of the heart. He

thought that experiments proved that the first sound was, like the second, valvular, and that muscular contraction and other causes to which it had been attributed had little or nothing to do with its production.

Dr. Arnold did not agree with him in regard to the conclusiveness of the experiments. At its last meeting this Association elected the following officers for 1875: President, Dr. John Dixon; Vice-Presidents, Drs. J. F. Monmonier, John Morris; Corresponding Secretary, Dr. W. H. Curry; Recording Secretary, Dr. S. K. Merrick; Treasurer, Dr. W. G. Regeater; Executive Committee, Drs. Taneyhill, Kemp, and Friedenwald; Committee of Honor, Drs. Murdoch, Eareckson, and Chew. After the election, the annual supper was held.

This is the season in which commencements appear to be epidemic. The Dental College graduated seventeen on the 25th ultimo; the Washington University twenty-six, on the 25th; the College of Physicians and Surgeons thirty-nine, on the 26th; and the University of Maryland forty-nine, on the 1st instant. The Maryland College of Pharmacy will close its session about the 10th, and then the bouquet-trade will be stagnant until the summer.

Yours, etc.,

MEDICUS.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

CONVERSATIONAL meeting, Wednesday, January 13, 1875.

VICE-PRESIDENT DR. J. S. ESHLEMAN in the chair.

Placenta prævia.

Dr. J. S. ESHLEMAN related a case of placenta prævia which he had treated in consultation with Dr. I. McGuigan. They met very soon after the first profuse hemorrhage had taken place. The pains were feeble, as is usual in these cases; the flow continued. The patient could not long survive it. The os would scarcely admit the tips of two fingers; it was from an inch and a quarter to an inch and a half in diameter. With Dr. McG.'s consent, he at once applied the forceps and brought the child's head firmly down upon the placenta, compressing it as well as the uterine sinuses, with the effect of instantly arresting the flow of blood.

Feeble pains were now stimulated, and aided by equable traction upon the instruments. The forefinger of the left hand was frequently interposed between the head of the child and the inner surface of the os to graduate the amount of force applied by the forceps held in the other hand, and, aided by the uterine efforts, the os in time began to yield. The uterus descended under the traction somewhat, but less than is often witnessed in natural labor. The case was conducted gently, each effort followed by rest in imitation of natural labor, and terminated in about one hour. There was no perceptible loss of blood, nor was there any concealed or post-partum hemorrhage. The child, though faint, soon rallied. The uterus closed softly upon the placenta, a portion of which remained firmly adherent near the os; the remainder lay protruding from the organ in a somewhat crushed condition, yet there was no hemorrhage. After this condition was

carefully examined by Dr. McGuigan also, he proceeded to dislodge the placenta, not by introducing the hand, "prating" or tearing it off, but by external pressure, moulding, and manipulation. Mother and child are doing well.*

He announced that Dr. McGuigan was present and would answer any questions relative to the case. He expressed his obligations to Dr. McG. for the opportunity and support he had given him, that enabled him to corroborate his recommendation to the members of this Society on a former occasion to conduct placenta prævia in the manner here presented.

Delay is attended with danger to the mother and certain death to the child. Turning is acknowledged a hazardous practice to both.

He is not aware that any one but himself has advocated this early introduction of the forceps for the purpose of arresting hemorrhage by compressing the placental and uterine sinuses, and for the purpose of dilating the uterus by means of the child's head as in natural labor.

Dr. WELSH asked where the placenta was attached.

Dr. ESHLEMAN replied, to the side of the uterus in greater part, and over the os in a measure.

Dr. GOODELL asked if the waters (membranes) had been broken.

Dr. ESHLEMAN replied that they had when he arrived. Dr. E. thought when that portion of the placenta covering the os had separated it shrank back so as to admit the membranes at the aperture.

Dr. GOODELL asked Dr. Eshleman to explain how the os was made to admit the forceps.

Dr. ESHLEMAN replied that the diameter of the os was less than the width of the blade of the forceps, but he was able in the absence of pains to elevate the head of the child, when the blade of the forceps would elongate the circular opening into the shape of a button-hole, so as to admit its passage; the second blade, being somewhat narrower, will pass over the shank of the first and enter the same aperture. It is surprising to test how small an opening will admit the forceps, and equally so how large a one is required to admit the hand.

In reply to Dr. Hamilton, he said that ergot was given in the hope that it would favor contraction of the emptied womb, but its effects could not be waited for to aid labor or depended upon to arrest hemorrhage.

Dr. MCGUIGAN, being present, was asked to give his statement of the case reported by Dr. Eshleman.

He stated that the day but one prior to her delivery, he found blood issuing from the vagina. She had lost a previous gestation by hemorrhage. The cervix was three-quarters of an inch in length, and he could feel the foetal envelopes, but not the placenta. Two days after, he found her bleeding, and in regular labor; the so open three-fourths of an inch, the membranes intact; the placenta could be felt three-fourths of an inch from the external os on the left side, and detached for the space of two inches. The pains were quick and forcible; the head was not engaged. He punctured the membranes when the pains became feeble and slow. The bleeding was not continuous during the two days mentioned.

Dr. ATKINSON said that the occurrence of placenta prævia in two succeeding pregnancies was exceedingly rare. Nor was there any reason to expect such a complication to occur again because a patient had once suffered thus.

In the only case that he had seen in which there was placenta prævia, it was almost completely central. There were no contractions. Ergot appeared to have no effect, although freely administered. He tore through the placenta, put on the forceps, and thus de-

* Recovered subsequently without an untoward symptom.

livered. The child had been dead for some time. The woman did well.

Dr. WILLIAM GOODELL then read a paper on "Head-Last Labors."

Dr. ATKINSON expressed his thanks to Dr. Goodell for this valuable essay. Especially to the young practitioner was this paper of great value. Almost continually we find children sacrificed to the timidity of the physician, who, fresh from the school and the warnings as to meddlesome midwifery, hesitates to do that which would save the infant. He was glad to find that a new school was being founded, in which the student is taught to aid the efforts of nature, rather than to sit by and wait for nature to do all the work.

Although he had repeatedly encountered head-last labors, he had never been compelled to use the forceps, but had always succeeded in speedily delivering by the method mentioned by Dr. Goodell. Supra-pubic pressure by the hand of an intelligent assistant, or, failing that, by the practitioner himself, he had always found of great value in speedily causing the head of the child to emerge.

Dr. BENJAMIN LEE was not sufficiently engaged in obstetric practice to be able to criticise the paper intelligently, but it appeared to him that little could be added to the extremely lucid and exact descriptions both of the mechanism of these presentations and the manipulations necessary to conduct them to a successful result. His object in rising was to confirm the lecturer's statement as to the great amount of traction which the neck would bear with perfect impunity. He was in the habit of treating his cases of spinal curvature, both lateral and angular, by means of modified suspension, the chin and occiput forming the points at which the force was applied, and the line of traction being thus in the direct axis of the spinal column. The head-straps, meeting above the ear, were attached to a steel bow just above the head, at the end of a long rope which passed over a pulley securely fastened to a stout joist. The patient takes hold of the other end of the rope, and draws down until the weight of the body is entirely sustained, the feet being raised from the floor. One-half of the weight was thus borne by the arms, and one-half by the neck; but the amount of traction was increased considerably beyond this from the fact that the patient swung himself often with much force. So far from this application of traction to the neck being unpleasant, it affords, in cases where the weight of the body was causing suffering by grinding pressure upon inflamed and ulcerated vertebræ, a delightful sense of relief, and he was often obliged to restrain his little patients in its excessive or too violent use. He did not hesitate to employ it where the cervical vertebræ were themselves the seat of the disease.

Dr. ESHLEMAN asked Dr. Goodell if he did not find in the living child that the cervical muscles contracted firmly when traction was made upon the head, thus giving important support to the spine.

Dr. GOODELL said he had so found it.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

WEDNESDAY, FEBRUARY 3, 1875.

DR. W. W. KEEN read a paper entitled "Experiments on the Laryngeal Nerves and Muscles of Respiration, etc., in a Criminal Executed by Hanging," of which the following is an abstract.

Dr. George Johnson had expressed the belief that while pressure on one recurrent nerve will cause direct unilateral palsy of the larynx, but not bilateral spasm or palsy, pressure on the vagus involving its afferent fibres may cause both. The reason of this he supposes

to be that the nerve-nuclei of both sides are so connected that each possesses bilateral activity. Dr. Mitchell having suggested the probability of a chiasm of the minuter fibres of the recurrens in man, which, though not demonstrated anatomically, might be proved physiologically, the following experiments were undertaken upon a criminal recently executed by hanging. After hanging about half an hour, the body of the criminal was cut down, and immediately examined. The left vagus and recurrent laryngeal were dissected as low down as possible in the neck, and the vocal cords examined while the nerves were excited by electricity. Repeated faradization with weak and strong currents, and galvanization with from four cells up to forty, of the recurrent and also of the vagus, produced decided movements of the left cord only, and none of the right. The wires were applied directly to each nerve, and the irritating action of a tumor simulated as nearly as possible. Careful dissection showed that in all probability none of the fibres of the vagus were injured.

The definite conclusion to be drawn from the experiment is that no chiasm of the inferior laryngeal nerves exists. No reflex motion was observed in the larynx, although the absence of this may have been due to violence done the parts by hanging.

Experiments upon the muscles of respiration were then undertaken. The left phrenic, having been insulated, was excited as in the previous experiments, but without result; no movements whatever of the chest were produced, nor was greater success obtained by one wire applied to the nerve while the border of the diaphragm was followed with a sponge, nor when both sponges were applied to the diaphragm.

The intercostals were then examined. Having been exposed from the median line to the line of the axilla, the interrupted current was applied to the intercartilaginous portion of the internal intercostals by means of small sponges, when it was found that they all raised the cartilage below them. The external intercostals were then faradized, when the upper rib was pulled down very markedly, while the lower one was just perceptibly raised; the movement increased from the first to the seventh, the last four not being examined. These experiments seemed to point to the conclusion that the internal intercostals are inspirators, and the external expirators.

The muscles of the face still retained their electromuscular contractility; but one was examined carefully, the pyramidalis nasi, which appeared as a result of the electrical excitation to act as the direct antagonist of the central portion of the occipito-frontal. Dr. Keen pointed out, in conclusion, the important results which this new method of investigation—the faradization of the muscles on the recently dead—promises to yield.

Dr. WHARTON SINKLER exhibited an office-battery made by Otto Flemming, No. 15 North Ninth Street, Philadelphia. The arrangement is a very convenient one, and enables the operator to use either the induced or the galvanic current at pleasure. The cost of the apparatus, complete, is \$180.

REMOVAL OF A NÆVUS OF THE UPPER LID BY MEANS OF A LIGATURE.—M. Talko records the case of a child aged ten months, who suffered from a telangiectasis of the upper lid one-third of an inch in diameter, a rapid cure of which was effected by passing two needles at right angles through the base, and tying a silk thread tightly around the base. No swelling of the lids followed; slight suppuration took place in the collapsed tumor which fell off in the course of a week, a clean wound being left. There was no puckering or retraction of the eyelid.—*Practitioner*; from *Centralblatt für Chirurgie*, No. 32, 1874.

SELECTIONS.

HILDEBRANDT ON THE TREATMENT OF UTERINE FIBROMA AND MYOMA BY HYPODERMIC INJECTIONS OF ERGOTIN.—Professor Hildebrandt, in the *Beiträge zur Geburtshülfe und Gynaekologie*, Band iii. Heft 2, 1874, remarks that recent literature has been lately very full of repeated trials of hypodermic injections of ergotin for the treatment of uterine tumors. As a rule, the result has not been favorable. Failure seems to have arisen chiefly from three causes: the extreme pain endured by the patient; phlegmonous inflammations and abscesses; and, in one case, poisoning. The strongest argument that has been used against it is, that those who have the hardihood to go through all the suffering have derived no benefit whatever. As to Dr. Hildebrandt himself, his experience has differed in no wise from that previously reported (*Berliner Klinische Wochenschrift*, No. 25, 1872), and he is perfectly satisfied with the results, which go to substantiate his previous assertions.

First objection: Pain.—The solution of ergotin now employed has 13 parts of water to 3 of the extract ergot, and 2 of glycerin. It causes less pain than when the quantities of water and glycerin were equal. The glycerin is added to prevent the formation of fungi. With this preparation, the pain is not greater than that usually experienced with the injection of quinine. The first applications are the most painful; the region of Poupert's ligament is the most sensitive spot, and that of the umbilicus the least so. There are two distinct varieties of pain; the first an immediate one, the effect of irritation to the cellular tissue, lasting a couple of hours; the second coming on later, and continuing for about an equal time, arising from contraction of the uterus. The latter kind of pain is essential to the success of the operation; the more severe it is, the more likely the desired effect will be obtained. Wernich's solution produces this pain also. The more deeply the needle is driven, the less intense is the first variety of pain.

Second objection: Phlegmonous inflammation and abscesses. Dr. Hildebrandt has never seen these accidents follow his own injections, and only twice where his assistants had operated; and this out of over one thousand hypodermic injections. These complications are believed to depend upon not inserting the needle deep enough; he passes the canula at least two-thirds of its depth, and does not mind injecting the fluid into the muscular tissues. The skin and its mediate superficial layer of cellular tissue should be thoroughly cleared. The experience of Langenbeck, Awater, and Löhlein coincides with his own, both as to this method of diminishing the pain, and obviating the occurrence of abscesses.

Kleinwächter's case of *poisoning* arose from the solution being too strong, three and a half parts nearly of ergotin to two of water and two of glycerin. The symptoms were analogous to those of morphia-poisoning: "deep stupor, reduction of temperature, pulse 140."

Against the negative results of other investigators he places the positive benefits obtained, as observed by Hermanides, Eggel, Bengelsdorf, Cl. Mayer, Keating, Hening, and Wernich; the latter having seen the treatment check hemorrhage in the majority of cases even after five or six injections, where it had been used solely for that object. Scanzoni writes him privately under date of March 30, 1874, that he is, as a whole, completely satisfied with his results, although he cannot flatter himself with ever having seen the entire disappearance of the tumor. He has used it in seventeen cases of large and small fibromata, the injections being persevered in for months. In one instance, a tumor midway between the navel and pubes diminished to the

size of an orange after forty injections. In a case of flooding from fibroma, it was arrested after the seventh injection. Dr. Burow writes privately to say that in one case a fibroid of the size of a child's head was reduced in three months to the size of an orange, with complete cessation of menorrhagia.

Dr. Hildebrandt now gives sixteen fresh cases, which occurred either in his own practice or under his immediate supervision, and divides them into three classes:—1. Removal of the symptoms, with reduction of the tumor; 2. Marked improvement of the symptoms, with slight reduction of the tumor (these were partly his own and partly others); 3. No effect either on the symptoms or on the tumors.

I. Removal of the Symptoms, with Reduction of the Tumor.—In the first division there are five cases, in women respectively of the ages of forty-three, thirty-four, twenty-eight (single), thirty-seven, and thirty-six years. In the first case, the tumor reached to the umbilicus; the uterus was moderately thickened and elastic. At the end of fifty injections, during two months, the tumor had receded to about the size of a three-months' gravid uterus. In the second case, the fibroma, about the size of a man's fist, was felt to be in the right side of the abdomen. With fifty-five injections, during three months, the tumor had ceased to be felt through the abdominal parietes. The small subperitoneal tumors which were noted before the operation were in no wise affected, except being more prominently felt. In the third case, that of a single woman, the tumor was nearly up to the navel; it was elastic, and distinctly demarcated from the surrounding organs. Twenty-six injections, during two months, diminished the tumor so much that its apex could be felt on a level with the pubes. At the request of the woman, the treatment was not continued. In the fourth case, the uterus was deeper than normal in the pelvis; the infra-vaginal portion of the cervix was not altered; the uterus was about the size of an apple. The uterine sound passed in 9½ centimetres (about 3¾ inches). There was profuse menorrhagia. In less than two months, after sixty-two injections, the uterine sound passed in 7½ centimetres (about 3 inches), and the body of the uterus was about the usual size of a multipara. In the fifth case, the uterus was universally enlarged to about the size of a small apple, with a fibroma in the wall on the right side; menstruation was excessive. With fifty-five injections, at intervals of two or three days, only half of the amount of solution being employed at times, on account of the pain, the uterus remained the same; but the tumor entirely disappeared. The tumor might have been only an exudation.

II. Marked Improvement of the Symptoms, with Slight Reduction of the Tumor.—Case 1. A woman (age not given) had menorrhagia of two and a half years' standing. The fundus of the uterus was about three finger-breadths above the pubes; a large fibroma was diagnosed on the right side of the uterus, extending into the cavity; it was firm and smooth on the surface. Sixty injections were made during nearly three months. At the end of the time the uterus was found to be on a level with the pubes, the menstruation had become normal, and the woman was able to move about again.

Case 2. The age of this patient is not given. The catamenia were regular as to time, but excessive in quantity and clotty. The uterus was as large as at the fourth month of gestation, anteflexed, with a subperitoneal fibroma as big as an apple in the left and upper side; an intra-uterine fibroma was also believed to exist. The uterus was firmly elastic. Fifteen injections were given, one every second day; the treatment could not be borne longer, on account of the suffering induced. Menstruation became normal.

Case 3. The patient, aged thirty-seven, had menor-

rhagia, with regularity, however, as to time. There were two uterine tumors; one subperitoneal, on the left side; the other, a larger one, intramural, in the posterior wall. Both were diagnosed as fibromyomata. Daily injections were used for a month, with an interval once of four days, from some phlegmonous inflammation showing itself around the seat of puncture. The next period was better, the tumor was slightly less, and perceptibly so; it was more readily felt, and more distinctly demarcated from its uterine parenchyma.

Case 4. In this woman, aged thirty-five, there had been excessive menorrhagia for the last two years. A large fibromyoma was distinctly defined, growing in the anterior wall, expanding the uterus above the pubes to about the size of the fifth month of gestation, at the same time descending deeply into the pelvis. Forty-seven injections were made in three months. The menses, which previously appeared every fourteen days, now had an interval of twenty-one and twenty-three days; their quantity was more normal, but they were still profuse. The uterus was a little smaller.

Case 5. In this patient, thirty-four years old, the catamenia appeared for the last twelve months every three weeks; they were excessive, with expulsion of clots. A fibroma about the size of a child's fist was diagnosed in the left wall of the uterus. Forty injections were made in three months. The fibroma became one-third smaller, the menses ceased, and pregnancy occurred, which pursued a normal course.

Case 6. A single woman, age not stated, had extremely profuse, painful menorrhagia every fourteen days, lasting eight or nine days. She had continued in this state for the last six years, and was extremely blanched. The uterus was anteflexed, broad, and extending a little above the pubes; the tumor had a firm consistence, with a smooth surface. Twenty-two injections were made during nearly two months. She became better in every respect; the catamenia appeared with an interval of twenty-nine days, continuing seven days. The injections were continued with good effect on the hemorrhage and benefit to the patient, without, however, producing any perceptible diminution of the tumor. This was in 1872. During the winter of 1873-74, in spite of the injections, the hemorrhage became freer, and for the time profuse. What was the exact cause of this return of hemorrhage the writer cannot say, but he thinks that the tumor (submucous?) might have descended, become seized in its downward course, which occasioned a temporary increase of bleeding.

Case 7. The patient was single, aged forty-seven. The uterus was the size of a man's head; menorrhagia was excessive, and she had leucorrhœa. Twelve injections were made. The menstruation was moderated, the periods being two days shorter. The tumor was unchanged; the fluor albus remained the same.

Case 8. This patient was aged thirty-five, with profuse menorrhagia every three weeks, of eight or ten days' duration. The fundus was felt midway between the navel and pubes; it was globular and firmly elastic. The cervix was patulous as far as the internal os. Twenty-five injections were made. The next period lasted nine days, but was moderate in quantity. The general condition was benefited. The uterus was two finger-breadths above the pubes.

Case 9. This woman was thirty-eight years of age; she had suffered from excessive menorrhagia for seven years. The last two years the menses had appeared every fourteen days, and there was a continuous intermediate sanguineous discharge. A slightly elastic tumor of the size of a fist was felt in the wall of the anteflexed uterus. After fourteen injections, menstruation became normal, for the first time for years. The tumor was somewhat smaller. Notwithstanding every precaution, phlegmon occurred twice in this case.

III. *No Effect on Symptoms or on Tumor.*—Case 1. The patient, thirty-seven years old, had a painful tumor on the right side of the abdomen. There was no leucorrhœa. Two tumors were found in the uterus; one, of the size of an apple, in the anterior vault of the vagina, connected with the anterior wall of the uterus; a second, somewhat smaller, in form like a normal uterus, seated on the right side of the walls of the uterus. Daily injections were made for fifteen days without producing the slightest alteration on the tumor. Case 2. The uterus was of the size of a man's head, with even surface and of hard consistence. There was profuse menorrhagia, with faintings. In Case 3, an old submucous fibroma was diagnosed; the patient derived not the slightest benefit from thirty injections.

Dr. Hildebrandt has again seen the first of his former published cases, after a lapse of two years. She came into the hospital with a five-months' child at the breast. He examined her, and found the uterus of normal size, without a trace of any abnormalities. In Case 5 of the same series the benefit continues, but the uterus is no smaller.

He believes it is essential, in order to obtain a successful result, that the tumor should be compressed by protracted contractions of the uterine walls. As, in neoplasms of other parts of the body, absorption can be produced by prolonged instrumental compression, so also may fibromyomata be reduced in size by similar compression by a tetanically contracted uterus. Whether the action of the ergot in causing contraction of the uterus and thereby compressing the tumor is the only way in which it operates, remains doubtful. In some cases, he is under the undoubted impression that the tumors soften before they lessen. If this softening were always present, it might be explained by supposing that the tumors, through an excess of blood in the veins, and a diminution in the arteries, as seen by direct experiment of Wernich, were gradually disintegrated. He protests against having ever maintained or believed that every fibroma of the uterus was capable of dispersion by ergotin injections.

The consistence of the tumor is all-important. An old impoverished fibroma, consisting chiefly of thickened connective tissue, is as unlikely to be absorbed as a calcareous mass. If the ergot increase the hemorrhage and discharge, it is probable that it does so by the uterine contractions causing a narrowing of the vessels. This is generally found to be the case in aged persons, the reverse, however, with the young; with the latter the tumors are vascular and loose, with muscular fibres. The most favorable cases are those which resemble in form and consistence a tense elastic cyst, which was the case with his first published case.

Energetic uterine contractions are essential to success; hence the uterus must be healthy and capable of contraction. Thin muscular walls are less fitted, as seen in some subperitoneal and submucous fibromata of large size, where the uterine walls are much expanded. In the intermediate-sized tumors, there is more risk of indurations and exudations into the parenchyma than there is from thinning. The cases the least suited are those where there have been some chronic parenchymatous metritis or perimetritis and parametritis. These conditions should be first cured before attempting injection of ergot. Lastly, the most favorable position is immediately under the mucous membrane,—the muscular layer that covers it being perfect. In the middle of the uterine walls it is less favorable, but least of all when subperitoneal. In the latter kind of cases he has at times observed the tumor pushed out, and thereby rendered more prominent, by injections.

In order to promote rapid absorption of fibromyomata, the following conditions are essential:

1. Their seat should be submucous.

2. Their consistence should be of a tense, elastic, muscular character.

3. The uterine walls should be healthy, contractile, not thinned by stretching, not unyielding through exudations, and the uterus free from perimetritis and parametritis.

He adds that whoever thinks he will cure the symptoms and remove the tumors by a few injections greatly errs. At least from twenty to fifty or more are absolutely necessary to obtain favorable results.—W. C. GRIGG, M.D., in *London Med. Record*.

GLEANINGS FROM OUR EXCHANGES.

SYPHILITIC ULCERATION OF THE ŒSOPHAGUS—DIAGNOSIS BY AUSCULTATION (HAMBURGER'S METHOD).—Dr. F. W. Godon gives an account of a case occurring under his care, in which the patient had suffered from dysphagia for six weeks. He had suffered some fifteen years previously from constitutional syphilis. There was no evidence of lung-disease, and he had no cough and no expectoration.

Examination of the throat and pharynx revealed nothing abnormal. The larynx also was found to be healthy, and there was no obstruction at the orifice of the Œsophagus. Only fluids could be swallowed.

The patient was made to drink a mouthful of water, and while he was swallowing it Dr. Godon auscultated the Œsophagus by Hamburger's method (detailed in the *Lancet* for May 30, 1874). By this means it was found that the water on reaching a point opposite the fifth dorsal vertebra was regurgitated with a loud splash; the fluid, however, was not thrown up into the mouth, but, at the expiration of a few seconds, passed down beyond the point of obstruction, and finally reached the stomach. By means of auscultation, a trickling or dropping could be distinctly heard during the passage of the liquid over the site of stricture, and the act of swallowing occupied some five minutes for its completion. Examination with a No. 8 bougie showed a tight stricture at the junction of the middle and lower thirds of the canal.

The case was diagnosed as one of syphilitic ulceration of the mucous membrane of the Œsophagus, and the patient was treated with iodide of potassium and ice, under which he rapidly improved. At the end of a month the disease had yielded so far that a No. 8 bougie could be passed without difficulty.

Notwithstanding this, a certain amount of thickening had taken place, and the patient was directed to continue the iodide at least two months, and was discharged with a guarded prognosis. Dr. Godon lays great stress upon the advantages of Hamburger's method in the diagnosis of these obscure affections.—*Pacific Med. and Surg. Jour.*, February, 1875.

A SIMPLE PROCESS FOR ESTIMATING UREA IN URINE (*The Practitioner*, February, 1875).—Mr. W. J. Russel describes a method for the estimation of urea, based upon a chemical reaction long known, but not hitherto available, on account of the elaborate calculations required.

Urea is decomposed by hypochlorous or hypobromous acid into water, carbonic acid, and nitrogen. If then the carbonic acid be absorbed by caustic soda, the gas evolved will be nitrogen alone, the amount of which will of course be an index of the urea. The apparatus used by Mr. Russel consists of a mixing-tube of such a form that the ingredients (hypobromate of soda, caustic soda, and the urine) can be introduced separately and mixed *in situ*.

This tube is inserted into the bottom of a water-bath of peculiar construction, figured by the author, and when the reaction commences the gas evolved is collected in a glass tube, so ingeniously graduated that the divisions are numbered to give the percentage of urea at a glance. The estimation is thus reduced to a matter of minutes, and the apparatus is certainly worthy of trial.

METRO-CEREBRAL DISEASE.—Dr. Percy Boulton, in a note to the *Obstet. Jour. of Great Britain and Ireland*, February, 1875, calls attention to the reflex disorders brought about by diseases of the uterus, the difficulty and the importance of properly distinguishing them. Headache, neuralgia, depression of spirits, hysteria, melancholy, epilepsy, pulmonic phthisis, cardiac irritation, dyspepsia, constipation, diarrhœa, flatulence, enuresis, are mentioned as a few of these reflex affections, and a case is related concerning a lady in whom the most threatening symptoms of melancholia were entirely dissipated by the cure of a diseased uterus. The inference drawn is that vaginal examinations should be made in many of the diseases of married women.

NOTES AND QUERIES.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Among the "Notes and Queries" to the *Philadelphia Medical Times* of February 27, 1875, is a note by Isaac Smith, Jr., M.D., headed "Criticism Corrected," in which certain charges of unfairness are laid to the door of "our critic;" and which, for his own sake, *our critic* feels bound to answer. They are—

1. That the article is not quoted "*candidly and honestly*," or "*in full*."

2. That what is quoted is done in a slovenly manner; and,—

3. The text seems to have been "*criticised*" without due regard to its "*subject matter*," either in "*letter*" or "*import*."

1. In this criticism, all I claim to do is to "copy the doctor's case in full." That I have done. The "twenty-three and a fraction of lines" were "omitted," as they had nothing to do with the case. They relate to Dr. S.'s speculations on it, and were therefore left out, although I confess they were exceedingly ingenious and amusing, as, indeed, the entire record is.

2. Whatever of "*slovenliness*" attaches to the part quoted is due, let me say, to the recorder, not to the critic; indeed, this quality might be said to pertain to the entire article. The history was quoted *verbatim*.

3. The case was criticised with reference to the "letter" of the "subject matter;" its "import" I supposed was contained in the "letter." To avoid even unintentional injustice, if Dr. Smith will kindly inform me of the true reading of the "subject matter," as regards both its "letter" and "import," I will, if wrong, gladly acknowledge my error.

"By the assistance of time," says Dr. Smith, "which is the great developer of all that is valuable in science, literature, and arts, as well as men, I shall also enumerate other syphilitic lesions which were evolved during the treatment of the case, and which were inadvertently omitted in my article."

Dear doctor, do not wait for "time" in giving the symptoms already "evolved;" give them now,—everything bearing on the case will be of value in explaining it,—and let future lesions, whatever they may be, be left to the "great developer."

NEW YORK, March 4, 1875.

FRED'K R. STURGIS, M.D.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

In the last number of your journal, March 13, an article appears by Dr. J. M. Boisnot on "A Case of Purpura Hæmorrhagica Requiring Transfusion," which requires some notice from me. On Sunday night, June 21, 1874, Dr. Boisnot wrote me as follows: "I am attending a case which will most certainly require transfusion, or something nearly as energetic, on account of the loss of blood from purpura hæmorrhagica. Can you come with the bearer? if not, please send word when. Bring apparatus and appliance for plugging nares."

I was out of the city, and, on my return the next morning, received another urgent message. With my private assistant, Dr. W. C. Cox, and the late J. T. Hopper, a student of medicine, and with the necessary apparatus, we reached Mr. Hirsh's at noon. The case was indeed a desperate one. After explaining the dangerous condition of the little patient, as well as the possible risks attendant upon the operation upon a child so young, transfusion was agreed upon. I then bled the father, debilitated the blood, and, with difficulty, opened the vein at the bend of the elbow in the right arm. I then readily, and very successfully, injected three syringefuls of blood; a violent chill with serious syncope followed. Very threatening symptoms continued for a considerable time, and slowly passed off. On going to see the child the following day, I met Dr. Fricke, and asked him to go in and see with me this interesting case. I have stated the above rather fully, perhaps, for the reason that, although so intimately connected with the case, I am, curiously enough, not even referred to, much less given any credit which may be due me for having performed an operation which certainly saved the child's life.

The operation from the beginning to the end was performed by myself; while I relied upon and received the principal assistance from Dr. Cox, who had been with me in all of my other transfusion cases. Dr. Boisnot, as well as the others present, aided me when called upon.

I would care very little about this, however, and would not have taken up so much of your valuable space, were it not that prior to and subsequent to the publication of my paper on "Transfusion," in the *American Journal of the Medical Sciences*, July, 1874, I answered inquiries from medical friends here and abroad respecting my cases and the apparatus used; and this last case occurring just at that time, and in a subject so very young,—probably the youngest on record,—led me to give, in several instances, the details of the case. It now appears either that my statements then given are without the least foundation, or that Dr. Boisnot has failed to present a complete history of the case, for he merely states that "transfusion of 3iv of blood from the father yielded a result beyond our most sanguine expectations." To whom "our" refers, the reader is not informed.

Very respectfully,
T. G. MORTON.

PHILADELPHIA, 1421 Chestnut Street, March 13, 1875.

DR. T. G. MORTON, 1421 Chestnut Street.

DEAR SIR,—I have received a copy of the current number of the *Medical Times*, containing an account of an operation of transfusion of blood performed on my son. I am much surprised that no mention is made of your name in connection with the case, as you personally performed the operation.

Respectfully,
LEOPOLD HIRSH.

PHILADELPHIA, 1318 Marshall Street, March 13, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—If I understand correctly the statement made in the "Therapeutic Notes," and also in the article on "The Use of Cold in Fever," in the number for February 27 of your valuable journal, referring to G. Mayer's paper in the *Jahrbuch für Kinderkrankheiten*, vii. 4, both articles contain a slight inaccuracy as regards the mode of administering the bath in scarlet fever. Your journal has it that Dr. Mayer "has been placing the child in a bath of from 93° F. to 73° F. for ten minutes, whenever the temperature rises above 102° F.," while Dr. Mayer places the child in a bath of from 93° F. to 88° F., and cools it gradually to from 77° F. to 73° F., whenever the temperature of the body exceeds 102° F.

In reading the description of Leube's ice mattresses, it occurred to me that it would be much easier and much more convenient to send for the undertaker to bring one of his patent corpse-preservers and place the patient in that to cool him off. He could have one or two blankets, and the window could be opened which is usually found at the head of these modern contrivances, and so enable him to get a sufficiency of that commodity, oxygen. By adding salt to the ice in the ice-compartment, any degree of cold desired might be produced, and the patient defervesced any number of degrees F.

This method would be particularly applicable in large hospitals, where the attending physician could order John to place the patient in the apparatus and put a thermometer in his axilla, and leave him there till the mercury reached 100° F. or 98° F.

I take it for granted that every physician of any experience is sufficiently familiar with this apparatus, so that it is not necessary to give a description of it; and I think few will deny that it would be effective.

M.

GERMANTOWN, March 9, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—In an article on Cold in Fever, you state that the only mention yet of cold baths being used in inflammation of the lungs is in an article by G. Mayer, in *Schmidt's Jahrbücher*, p. 347. But in the last vol., No. 5, of Von Ziemssen's *Handbuch der Speciellen Pathologie und Therapie*, just published, the first article is on pneumonia, by Prof. Theo. Jürgensen, and his sole treatment in that disease is by cold baths, and also quinia, of which he gives thirty grains at a dose.

He also uses wine before and after the cold bath. The whole number he treated with cold baths and quinia wine is two hundred,—one hundred and fourteen males, eighty-six females; died, twenty-four,—and of these twenty-four, all were complicated. Not one died of acute pneumonia, but eight of delirium tremens, two of abortion, two of pertussis, four of peritonitis chronica, and the other of pericarditis. He says that his death-rate may speak for itself.

One of his maxims is, Never forget that the worst enemy the heart has is the high temperature; and this is certain to be reduced by the use of cold baths.

Truly, yours,
C. H. SMITH.

KENTON, OHIO, March 7, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Under "Therapeutic Notes" in your number of February 20, you speak of "A New Poultice," and omit an important point in so doing.

The poultice Lelièvre is prepared by saturating cotton-wadding with a very mucilaginous decoction of carrageen, pressing and drying it. This then admits of being "cut into thin plates" and used as your article describes, and possesses all the advantages therein enumerated.

I have made some of it at the request of Dr. Hewson, and I believe that it is now made and in use at the Pennsylvania Hospital, giving great satisfaction.

Very truly, yours,
GEORGE J. MCKELWAY.

We have received a letter from one of our Western correspondents, making the gravest charges against H. V. Sweringen, of Fort Wayne, Indiana, a paper by whom was published in the issue of the *Philadelphia Medical Times* for February 27. At this distance we are, of course, unable to give an authoritative opinion in regard to these charges, but assert, without hesitation, that Mr. Sweringen has been guilty of the gravest breach of professional etiquette, not to say common honesty, in sending to a distant medical journal a medical article, and then having it published in a local newspaper, and himself and newspaper afterwards editorially puffed because the *Times* had copied his article from the newspaper. The editor of the *Times*, not being omniscient, cannot always detect the disguises of Satan, but can only point out the true nature when the cloven foot appears.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—In my article on organic matter in drinking-water in your last issue, I suppose no person on second thought would *extemporaneously* prepare Nessler's reagent and use potassium iodide by the *pint*; yet if *part* were substituted, so as to read, "one part of salt to twenty parts of water," it would be at least more practicable.

Very truly, yours,
CHARLES MCINTIRE, JR.

PHILADELPHIA, March 9, 1875.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

THE next conversational meeting will be held at the hall of the College of Physicians, Wednesday, March 24, at 8 o'clock P.M.

Dr. Joseph Leidy will lecture on the "Anatomy of the Ear."
The medical profession in the city are cordially invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MARCH 9, 1875, TO MARCH 15, 1875, INCLUSIVE.

O'REILLY, R. M., ASSISTANT-SURGEON.—Granted leave of absence for twenty days. S. O. 28, Department of the Platte, March 5, 1875.

MUNN, C. E., ASSISTANT-SURGEON.—To report in person to the President of the Army Medical Board, New York City, for examination for promotion, and, upon its completion, to return to his proper station. S. O. 39, A. G. O., March 8, 1875.

SATURDAY, MARCH 27, 1875.

ORIGINAL COMMUNICATIONS.

METHODS OF PHYSICAL INVESTIGATION IN DERMATOLOGY.

BY HENRY G. PIFFARD, M.D.,

Clinical Professor of Dermatology, University of New York; Surgeon to Charity Hospital, etc.

IN the investigation of cutaneous phenomena we are able to avail ourselves of the assistance afforded by three of the special senses,—those of sight, smell, and touch,—supplemented and sometimes rendered more precise by various instrumental aids.

Our unaided eyes enable us to judge of the color, form, and distribution of the various lesions or objective manifestations of disease; while with the aid of a lens we are able to observe fine surface-markings, to define more accurately the form of minute lesions, and more easily to detect certain parasites.

Heretofore the single lens or simple microscope has been the main reliance for this purpose. This instrument, though convenient, is limited in its application to cases in which only a slight degree of amplification is desired.

The difficulties which surround the attempt to study the cutaneous surface with simple lenses of high power are mainly the following: The shorter the focus of the lens, the nearer it must approach the object; the illumination is diminished; the field of view is contracted, and the spherical aberration becomes so evident as materially to jeopardize the accuracy of the observation. In addition, the shorter the focus, the nearer must the eye of the observer be approached. This often involves a constrained position of the head and neck, and, in some cases, an unpleasant proximity to the subject under investigation.

To obviate these inconveniences, and at the

same time to obtain a comparatively high amplifying power, I was led to adapt the compound microscope to the purpose in view. The arrangement of the instrument* which I employ will be readily understood from the accompanying cut.

A represents the body of a binocular microscope made by Nacet, from which the reflecting prism situated above the objective was removed, and another of the same form but double the size substituted. B is a double nose-piece carrying two objectives of different powers.

C is the pinion for fine adjustment, and D the clamp-

ing screw for coarse adjustment. E is a rod five feet in length, which supports the other apparatus, and is itself supported by a cast-iron foot not shown in the drawing. Other adjustments permit the body of the microscope to be placed in a horizontal or any other desired position.

The objectives which I employ are a 6", 2", and 1", of Grunow, a 4" and $\frac{1}{2}$ " of Ross. The $\frac{1}{2}$ " is made with taper front, specially constructed for use with reflected light.

The advantages of this arrangement over the single lens are enlargement of the field of view, absence of spherical and chromatic aberrations, convenient distance of the observer's eye from the object observed, ten times the amplification practically attainable with the simple microscope, and, lastly, the very great advantage of true stereoscopic vision.

With the instrument described, any portion of the integument from the scalp to the sole of the feet can be conveniently examined, and a prolonged examination can be made without fatigue to the observer.

It is an instrument which I cannot too highly recommend to those desiring a thorough knowledge of the surface-aspect of the skin and its lesions.

Pursuing our investigations deeper, we have the ordinary methods of the laboratory at our command. These, as applied to dermatology, consist in removing small pieces of skin from the living or dead subject, hardening them in some preservative solution, and finally cutting them in thin slices, or sections as they are called.† These thin sections are then examined with the ordinary compound microscope.

This field of investigation has been specially worked by the German dermatologists, and it is to them that we owe most of our knowledge concerning the minute anatomy of skin-lesions. Americans, however, have contributed something to this branch, as the researches of Derby, Geddings, Haight, Warren, Young, and others testify. It is but just to add, however, that the investigations of these gentlemen were mainly conducted at Vienna, and under the mantle of the German school. The French and English have done little in this department, except in connection with the parasitic affections. The anatomy of the normal skin, however, has been best studied by the French, the names of Breschet and Sappey being specially memorable.

It is sometimes desirable to obtain thin sections of morbid skin for microscopical examination in a perfectly fresh condition and unaltered by reagents. This may be accomplished by means of a little instrument called the cutisector, which I devised some years ago,‡ but have since improved, giving it the form shown in the cut (Fig. 2).

It consists of two sharp, parallel, semilunar blades, which, by means of a screw, can be adjusted at a definite distance from each other. If, with the

FIG. 1.

* A notice of the instrument has been previously published in the Archives of Dermatology, vol. i. No. 2.

† For full details of these procedures the reader is referred to the standard text-books of histology and microscopical manipulation.

‡ Am. Jour. of Syph. and Derm., July, 1870.

instrument held as a pen, a cut be made through the skin, there will result two incisions, including between them a thin slice of integument. This is afterwards removed (though it sometimes comes out with the instrument), and may be immediately examined under the microscope, a drop or two of some indifferent fluid being added. The operation may be facilitated and rendered painless by previously congealing the part with ether spray.

The sense of smell sometimes affords us information in connection with certain affections, *e.g.*, smallpox, favus, bromidrosis, etc. Its applications in dermatology, however, are as yet quite limited.

The sense of touch, on the other hand, renders us extremely valuable services. By it, in the first place, we are enabled to judge to a certain extent of the temperature of any portion of the skin. This point, however, can be investigated more accurately by means of Seguin's surface-thermometer (Fig. 3).

With this instrument the temperature of a skin-lesion of very limited extent may be readily ascertained, and comparisons with corresponding healthy points effected.

The sense of touch further enables us to judge of the comparative roughness and smoothness of different portions of the integument, and also of varying degrees of dryness or moisture.

Until recently the *tactus eruditus* was to the gynecologist the all-important aid to the physical diagnosis of uterine disease, and even now affords him information not otherwise attainable. In like manner the "educated touch" can be made to render the greatest services to the dermatologist, and I never omit the opportunity of impressing upon students the desirability of using not only their eyes

but also their fingers in the study of the affections of the skin. If the mind be concentrated upon the finger-tips, with the eyes closed, and careful palpation of skin-lesions be practised, it is surprising how soon the sense of touch becomes educated to a point which enables it to furnish valuable information, occasionally detecting lesions or peculiarities that would otherwise have escaped notice.

Having practised this method to a considerable extent, I feel confident that it will amply reward all who take the trouble to cultivate it.

A very useful instrumental aid in the study of certain cutaneous phenomena is the *æsthesiometer*. I prefer the form here shown (Fig. 4). It is an

improvement by Carroll upon Hammond's earlier instrument.

With this instrument the sharp points are used in the determination of the sensibility to pain, while the blunt ones serve for the detection of the acuteness of the tactile sense.

This instrument may also be conveniently employed for the measurement of the extent of patches of eruption, the divided scale being graduated in both inches and centimetres.

Dermatologists have not as yet availed themselves of some of the aids to investigation above noticed to anything like the extent which their importance warrants, trusting in most instances to their unaided senses; but for the future it should be remembered that those who depend upon good eyes alone, even with good brains behind them, will often fail to obtain valuable information which the less gifted observer, aided with instruments of precision, will readily acquire.

CLINICAL NOTES ON FORTY CASES OF CHOREA.

BY CHARLES K. MILLS, M.D.,

Philadelphia.

Chief of Dispensary for Nervous Diseases, University Hospital.

FOR sixteen of the cases included in the following table and appended notes, I am indebted to H. C. Wood, Jr., M.D., Clinical Professor of Nervous Diseases in the University of Pennsylvania. The rest have fallen under my own immediate care in private and hospital practice. I have resorted to the tabular method for the sake of convenience, and in order to give the most facts in the least space. Readers of the *Medical Times* will recall a brief but valuable "Report on Thirty Cases of Chorea," by Dr. George S. Gerhard, in the issue of the journal for January 3, 1874.

NO.	SEX.	AGE.	SEASON.	VARIETY.	APPARENT CAUSE.	HEREDITARY INFLUENCE.	TREATMENT.	RESULT.
1	F.	13	Spring.	Right.	Rheumatism.		Arsenic.	Marked improvement.
2	F.	10	Winter.	Right.	Rheumatism.		Arsenic, iron.	Cure.
3	F.	10	Spring.	Right.		Father intemperate.	Cimicifuga.	Cure.
4	F.	20	Spring.	Right.	Fright.	Father intemperate.	Gentian, valerian, arsenic, iron.	Cure.
5	F.	9	Spring.	General.		Cousin epileptic.		
6	F.	13	Spring.	General.	Rheumatism.		Cimicifuga.	Improved.
7	M.	11	Summer.	Left.		Mother melancholy.	Bromide of potassium.	Marked improvement.
8	F.	16	Spring.	General.	Hard work.	Father phthisical. Sister had chorea.	Bromide of potassium and chloral.	Cure.
9	F.	8	Summer.	General.	Fright.	Father insane.	Bromide of potassium, chloral, zinc, arsenic, iron.	No improvement.
10	F.	16	Winter.	Left.	Hard study.		Arsenic, iron.	Cure.
11	F.	15	Spring.	Larynx.	Rheumatism.		Arsenic.	No improvement.
12	F.	8	Winter.	Hands.	Fright.		Arsenic, iron.	Improved.
13	M.	8	Winter.	Left.		Mother phthisical. Father intemperate. Upper incisors notched.		
14	F.	11	Spring.	Both sides, but chiefly left.		Father intemperate. Upper incisors notched.	Arsenic, iron.	Cure.
15	F.	8	Spring.	Right, afterwards general.	Fright.	Father melancholy. Aunt and brother had chorea.	Arsenic.	Cure.
16	F.	21	Spring.	Arms and head.	Fright.	Upper incisors notched.	Arsenic	Improved.
17	M.	9	Spring.	Right.	Fright.	Father intemperate.	Gentian, valerian, arsenic, iron.	Cure.
18	M.	7	Spring.	Eyes.		Father intemperate. Upper incisors notched.	Arsenic.	Improved.
19	M.	6	Summer.	Both sides, but chiefly right.		Upper incisors notched.	Arsenic.	Improved.
20	F.	8	Winter.	Left.		Upper incisors notched.	Arsenic.	Improved.
21	F.	7	Winter.	General.	Rheumatism.		Arsenic, iron.	Marked improvement.
22	M.	4	Spring.	Right.	Tinea capitis.	Father phthisical.	Cimicifuga, iron.	Cure.
23	F.	7	Spring.	General.	Rheumatism.		Arsenic.	Improvement.
24	M.	13	Spring.	General.	Rheumatism.		Cimicifuga.	No improvement.
25	F.	7	Spring.	General.			Cimicifuga, iron.	Cure.
26	F.	15	Spring.	Right.	Establishment of menstruation.		Arsenic, iron.	Cure.
27	M.	14	Autumn.	Arms and head.			Arsenic	Marked improvement.
28	F.	12	Autumn.	General.	Fright.	Father intemperate.		
29	F.	15	Spring.	Right.	Rheumatism.		Arsenic, iron.	Cure.
30	F.	13	Spring.	General.	Hard study.		Arsenic, iron.	Improved.
31	F.	12	Spring.	Left.		Three other children had convulsions.		
32	F.	6	Spring.	Left.	Blow on head.		Arsenic, iron.	Cure.
33	F.	9	Spring.	General.		Paternal uncle had chorea.	Cimicifuga, cinchona, iron.	Improved.
34	F.	6	Autumn.	Left.	Rheumatism.	Upper incisors notched.		Cure.
35	F.	10	Autumn.	Left; chiefly left hand.	Rheumatism.		Arsenic, iron.	Cure.
36	F.	15	Autumn.	Right; chiefly right ear.	Establishment of menstruation.	Father phthisical. Aunt hysterical. Sister insane.	Arsenic, iron.	Marked improvement.
37	F.	13	Winter.	Right; chiefly right hand.	Rheumatism.	Mother nervous; has lost seven children under two years old.		
38	F.	9	Winter.	General.	Rheumatism.	Mother melancholy.	Bromide of potassium, iron.	Cure.
39	M.	17	Winter.	Right.		Sister had chorea.		
40	F.	17	Spring.	General.	Fright.	Father phthisical.	Bromide of potassium.	Cure.

Recapitulation.

Sex.—Males, 9 cases; females, 31.

Age.—Ten years and under, 20; from ten to twenty-one, 20.

Season.—Spring, 23; summer, 3; autumn, 5; winter, 9.

Variety.—General, 11; right, 12; chiefly right, 1; left, 8; chiefly left, 1; arms and head, 2; local (larynx, 1; hands, 1; eyes, 1), 3; not recorded, 2.

Apparent cause.—Rheumatism, 12; fright, 8; hard work, 1; hard study, 2; tinea capitis, 1; establishment of menstruation, 2; blow on head, 1; no cause discovered, 13.

Hereditary influence.—Males 7, females 17; total 24. I have not confined myself to a search for nervous diseases in order to determine the fact of hereditary influence, but, as the table shows, have carefully sought for any cachexiæ, diseases, or abuses in the ancestry or collateral relations of the patients. Notching of the upper incisor teeth—the so-called "Hutchinson teeth"—I have regarded as evidence of inherited syphilis.

Results of treatment.—Cures, 17; marked im-

provement, 5; improved, 8; not improved, 3; result not known, 7.

Remedies successfully employed.—In this recapitulation I include the cases cured and improved, 30 in all. Arsenic, 7; arsenic and iron, 12; arsenic, iron, valerian, and gentian, 2; cimicifuga, 2; cimicifuga and iron, 2; cimicifuga, iron, and cinchona, 1; bromide of potassium, 2; bromide of potassium and chloral, 1; bromide of potassium and iron, 1.

Doubtless some of the cases not reported as cures should be embraced in this list, as patients who get well often fail to return.

Arsenic was usually exhibited in the form of Fowler's solution, commencing with three or four drops thrice daily, and increasing the dose until about ten drops were reached, carefully watching, of course, for symptoms of poisoning. Iron was given as the bitter wine, the tincture of the chloride, or the syrup of the iodide, sometimes in separate prescriptions, and sometimes in combination with the other remedies employed. Cimicifuga was generally used in the form of the fluid extract, taking care to have a good article, and beginning with

doses of one-half fluidrachm, which were gradually increased, unless toxic effects were produced. The following formula was employed in two cases :

R Liq. potass. arsenitis, fʒi;
Tinct. valerianæ,
Tinct. gentianæ comp., āā fʒi.—M.

Sig.—Teaspoonful in water three times daily.

The compound tincture of cinchona was combined with the cimicifuga and iron in one case. Bromide of potassium was ordered in doses of from ten to twenty grains. Bromide of potassium and hydrate of chloral in combination were strikingly serviceable in one instance. The chloral was administered in amounts of five grains.

In four cases in which cimicifuga was first prescribed, it proved unsuccessful, or could not be tolerated by the patients. All of these cases afterwards improved under arsenical treatment. In one instance, cimicifuga in combination succeeded after arsenic and iron had failed.

With zinc, which is strongly recommended by many writers, I have had but little experience. The sulphate was given without success in two of the forty tabulated cases, one of which was afterwards greatly improved by arsenic, while the other did not yield to any treatment adopted.

General faradization and galvanization, as recommended by Benedikt, was temporarily used in three or four cases, without benefit; but I have not yet given electricity a fair trial. I have never tried the purgative plan of treatment. Cold affusion upon the spine was ordered as an adjunct to other treatment in four or five cases; but one cannot depend upon this measure being carried out strictly unless the patients are under constant supervision. Good, nutritious diet was always advised.

In the seventeen cases cured, the average duration of the disease before treatment was between five and six weeks, and under treatment also between five and six weeks, making the average entire duration about eleven weeks. The shortest time required to effect a cure was two weeks; the longest, four months. Two cases were cured each in three weeks.

The following are some points of interest not brought out in the table:

One previous attack had occurred in ten cases; two in one case. In two cases the disease had persisted for two years, and in one for three, with brief intervals of improvement. In twenty-five cases the disorder came on gradually; in fifteen the onset was sudden, so far as could be judged from the statements of patients and their friends and relatives.

Cardiac murmurs were observed in seven cases, five of which were associated with rheumatism.

Establishment of menstruation is given in the table as the apparent exciting cause in two cases. In eleven others the ages of female patients ranged from twelve to seventeen years. In four of these eleven I have noted the fact that the chorea came on shortly after the initiation of the menses, but have recorded rheumatism as the apparent cause, a rheumatic history having been discovered.

In five cases parents reported that the choreic movements continued during sleep.

One of the cases had formerly been a somnambulist.

Headache was noted in eight cases.

Spinal tenderness was found in four cases out of ten examined for this symptom: in two in both the dorsal and lumbar regions, in one in the dorsal, and in one in both the cervical and lumbar.

In four cases partial paralysis was observed and recorded: of the right side, of the right arm, of the right leg, and of the left arm, each in one case. Unfortunately, my notes are not full in regard to paresis and paralysis.

I will briefly detail half a dozen cases which present points of special interest in regard to such matters as hereditary influence, the effects of or resistance to treatment, association with hysteria, and peculiar localized movements.

Case I.—C. K., æt. 16, who had been overworked in a factory, fell under my care May 4, 1871. An attack of general chorea had come on a few days before. The so-called "insanity of the muscles" was as well illustrated in this case as in any which I have ever seen. Her movements were exceedingly violent and grotesque. She could not walk nor stand, and a bed had to be made for her on the floor. At first one leg, then another, and then an arm, would be suddenly hurled into the air; the whole body would be tossed upward; the head moved and twisted in every direction possible; and she grimaced and contorted her countenance frightfully.

This girl's father was a consumptive, and one of her sisters had had a severe attack of chorea.

Under the use of bromide of potassium, gr. x, and hydrate of chloral, gr. v, every three hours, she got well in two weeks, the shortest time in which I have known recovery take place, although the case was one of the worst which has fallen under my notice.

Case II.—K. S., æt. 8, a bright, precocious-looking girl, was first seen by me June 24, 1871. One week before, she had been frightened at school, from which time she was restless and began to twitch. She got rapidly worse, and when I first saw her was suffering from severe general chorea. She could not stand. Her arms and legs and head were in a constant state of motion. Articulation was almost impossible, and deglutition was difficult.

The father of this patient was insane, and had at one time been an inmate of the Philadelphia Hospital for the Insane.

I treated her for nearly four weeks with bromide of potassium and chloral, with sulphate of zinc, and with arsenic and iron, but with no persistent improvement, when she was sent to a hospital. In the neighborhood in which this child lived was a sausage-factory, which, when in active operation, kept the doors and windows, and, in some instances, the buildings around it, in a constant state of pronounced vibratory motion, and thus seemed to aggravate the symptoms of the disorder and interfere with recovery.

Case III.—S. M., æt. 16, was first seen January 28, 1874. She had been going to school and studying hard until recently. Five weeks before coming for treatment, it was noticed that she talked a little "thick." Three weeks later, she began to toss her head, throw her left arm about, and walk in an irregular, stumbling manner, jerking the left leg out from the body. On one occasion she burned her left hand on a stove, because of her inability to govern her motions. She grimaced almost continually; and her mother stated that she was fretful, and laughed or cried for the merest trifles. I could discover no spinal tenderness. The

sclerotic coat had a peculiar bluish tinge. Now and then for several weeks she had experienced a little pain in the arms, probably rheumatic. For a few days, at intervals, she had pain in the foot and in the knee. An endocardial murmur was detected. Her appetite and digestion were good, respiration easy, bowels and water regular. Her menses had been established when she was fifteen, and had appeared regularly. No hereditary taint could be traced. Her father died when she was seven years old, of typhoid fever; her mother was living and well, and she had two brothers and four sisters, all of whom were healthy.

The case was one of pretty well marked left hemichorea, and I at once put her on Fowler's solution, four drops three times daily, which was increased in dose until eight drops were given. I also prescribed tincture of the chloride of iron, ten drops three times daily. Under this treatment the patient improved constantly, and was cured in four weeks.

Case IV.—A. P., æt. 15, whose father and mother were both living and well, came under observation March 11, 1874. She had been a healthy child until she was eight years old, when she had an attack of inflammatory rheumatism. One year later, she was frightened by a fire occurring in the house, became nervous, and had been so ever since. About ten months before applying for treatment, she gave evidences of marked chorea, twitching various muscles, and throwing her limbs about wildly. She got so bad that she could scarcely be held, and was treated by several physicians. Her menses had appeared for the first time within a few weeks. She had not been entirely free of choreic symptoms up to the time of presenting herself; and about three weeks before this period the most striking and peculiar symptom of the case appeared. This was a short, hoarse, barking cough, which had continued day and night without intermission, excepting when the patient was intently reading or was fast asleep. It seemed to correspond to the tussis hysterica or nervous cough of writers, and was, apparently at least, involuntary. No disorder of the lungs could be determined by physical exploration. The patient complained of soreness of the throat; and the fauces and tonsils were found somewhat inflamed, but this condition may have been secondary,—the result of irritation produced by a cough purely nervous.

The patient had been troubled with constipation ever since she was about eight years old. She would often go five or six days without an evacuation of the bowels, and on one occasion had gone as long as thirteen days. She frequently had pains in the abdomen, and examination showed the existence of fecal accumulations.

She was placed upon Fowler's solution, and a pill of the extracts of belladonna, colocynth, and gentian; and she was also ordered cold affusion to the spine, and a gargle of chlorate of potassium; but she only remained under observation about ten days, during which time I could discover no improvement of any moment in the symptoms.

In this case chorea and hysteria were probably associated, a combination of disorders which my experience would lead me to believe is not uncommon. Large quantities of limpid urine were voided by the patient daily; a secretory derangement which, it is well known, is generally present in hysteria.

Case V.—S. A. W., æt. 11, a school-girl, fell under my care April 1, 1874. Two months before, her mother first noticed at the table that she could not use her left hand properly. She would let things drop. In going around the house, she walked in a strange, irregular manner, throwing her limbs about somewhat wildly. She could not sit still. She had been getting gradually worse. She had choreic twitchings of the fingers and

limbs of both sides, but more particularly the left. The left hand and foot showed some loss of power; she dragged the latter a little in walking. Her face was not affected; and she could speak, swallow, and thrust out her tongue properly. She had occasional frontal headaches. Spinal tenderness was found over the sixth and seventh dorsal and first lumbar vertebræ. No history of rheumatism, no heart-murmurs, and no exciting cause could be discovered.

Hereditary influence seemed to be a highly important factor in this case. The father of the patient was a nervous, excitable man, subject to fits of melancholy; a brother had had chorea, as had also the father's sister, when about sixteen years of age.

She was ordered Fowler's solution, beginning with four drops three times daily, and increasing, and also the bitter wine of iron. She was discharged, well, April 25, having been under treatment about three weeks. The arsenical preparation was stopped for two or three days during this time, because of puffiness of the eyelids and pain in the stomach.

Case VI.—M. H., æt. 15, a school-girl, came under observation December 29, 1874. Her father has marked symptoms of phthisis. Her father's sister is hysterical. She has one sister, thirteen years of age, who is insane.

Her menses came on six months before presenting herself for treatment, since which time she has been nervous and delicate. She was quite well before menstruation began. During the last two months she has menstruated every two weeks instead of every four. She presents no history of rheumatism or fright. Her bowels are regular and appetite good. She has occasional headaches. She went to school until three weeks ago, and was a good student. She looks dejected and miserable, and says that she feels melancholy.

Two months ago her right ear began to twitch, or move up and down. Her nostrils and upper lip also soon became affected with twitchings; and within a few days slight choreic movements had extended to the entire right side of the body.

The movement of the ear was quite peculiar; it continued nearly all the time, even when the patient's attention was not directed to the part, according to the statements of her mother. The attollens aurem or superior auricular muscle, whose office is the elevation of the ear, and which, with the other extrinsic muscles of the ear, generally has no active vocation in the human species, although important in some of the lower animals, was energetically brought into play in this case.

The ear was constantly moved up and down, sometimes slowly and sometimes rapidly. The act seemed to be partially under the control of the will. By a strong effort the left ear could also be moved very slightly in the same direction. The mother of the patient did not think that the movement continued during sleep.

The patient was ordered to be kept from school, where the motion of her ear drew the attention of the scholars to her, and thus made her more nervous. Good food, pure air, and pleasant company were also advised. The following prescription was given:

R Vini ferri, f3vi;
Liq. potassii arsenitis,
Syrupi, aa f3i;
Aquæ, f3i.—M.

Sig.—Teaspoonful in water after meals; the amount to be gradually increased.

Under this treatment, her general health improved rapidly. All the movements, except those of the right ear, ceased entirely. At the time of making these notes, two months after the girl was first brought for treatment, the motion of the ear still persists, although the

patient seems to be quite well in other respects. For a short time—after she had been under treatment about a month—the ear did not work unless especial attention was called to it; but the local affection, although improved, has not been cured.

A CASE OF RETINAL HEMORRHAGE.

BY SWAN M. BURNETT, M.D.,

Knoxville, Tenn.

MR. D. was sent to me on the 20th of June, 1874, by his physician, on account of ocular trouble. He had been in bad health since the summer of 1873, when he had cholera, and, immediately after, what his physicians called typhoid fever. Three days before I saw him, while in the country, still quite weak and feeble, he stooped down to pick up a small bit of wood, and, on rising up, found himself totally blind in both eyes. In the course of a few seconds vision in the right eye returned, but a large scotoma remained in the left, which was the cause of his visit to me. I found central vision entirely lost. The scotoma at the distance of six feet was about one and a half feet horizontally and one foot vertically at its widest part. At first it appeared black to him, but at this time it has a reddish tinge. It is of a pyramidal shape, the base occupying the centre of the visual field, while the apex points outwards and downwards.

An ophthalmoscopic examination revealed an extravasation of blood in the retina, having the shape he gave to the scotoma. The apex of the pyramid lay just below and a little beyond the nasal edge of the optic disk, while the base was about two diameters of the disk distant from the temporal edge. The upper edge of the pyramid lay at the lower edge of the disk. The color of the effusion was dark red; it was non-striated, and its boundaries were not sharply defined, especially the lower one. The retinal vessels seemed to lie under it. At the apex was a large vein which was apparently the origin of the hemorrhage. The fundus was otherwise normal. No treatment was advised.

On the 5th of July I examined the case again. The extravasation was fully one-third smaller, and had contracted about equally in all its dimensions. There was now a space between its upper edge and the edge of the optic disk, and in the space were seen some vessels passing beneath the clot and emerging on the other side. The corners of the pyramid were more rounded, and the edges were more clearly marked. No appearance of striation. Subjectively the scotoma has considerably reduced, and is not so dense, but still has the reddish tinge.

After this the patient went to the country, and I did not see him again for a month. By this time the scotoma had entirely disappeared, leaving a very slight haziness in the place in the visual field it had occupied. He reported that after the last examination it had gradually reduced in size and lessened in density until it reached its present condition.

An ophthalmoscopic examination showed nothing at the former site of the effusion, but a very little turbidity of the retina.

He has had up to this time no return of the extravasation.

Our text-books on ophthalmology say very little about retinal hemorrhage, except as a concomitant of retinal hyperæmia or inflammation. Some, it is true, mention the fact that it may occur in diseases of the heart and kidneys, and in degeneration of the vascular walls, and in menstrual derangement,

but none give it any considerable attention. Dr. Bull, of New York, gives in the *American Journal of the Medical Sciences* for April, 1874, the most elaborate article on the subject to be found in our more recent English literature, while Pagenstecher and Mandelstanow in Germany have reported and commented upon a large number of cases occurring in the clinic at Wiesbaden.

Dr. Bull advances the opinion that retinal hemorrhage is to be looked upon often as a precursor of cerebral apoplexy, and cites three instances under his own observation, and some from other sources, where this was the case.

Where the extravasations are numerous and oft-recurring, I have no doubt that cerebral hemorrhage will be likely to follow retinal effusion, for under these circumstances the condition of the vessels and circulation would be such as to render an extravasation liable to occur at any point and at any time; but I do not see why a single effusion, from perhaps a temporary cause, should lead us to look for subsequent cerebral hemorrhage.

His heart was examined by myself and several other physicians, and no evidence of organic disease was discovered. An examination of his urine failed to show evidence of kidney-trouble.

One feature in our case deserves notice. Though the extravasation was in the anterior layers of the retina, as evidenced by the passage of the retinal vessels under it and the non-implication of the percipient retinal elements, it did not have that striated appearance which extravasations in that position are generally represented as having. It will also be observed that the scotoma, except for the first few hours, did not have a perfectly opaque appearance, but was of a reddish tinge. In such cases, it seems to us, the color of the scotoma might have some prognostic importance. In our case the reddish tint of the scotoma showed that the retinal elements behind the extravasation must be intact, because they were affected by the red rays transmitted through the blood-clot; otherwise the scotoma would have been perfectly black.

NOTES OF HOSPITAL PRACTICE.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

SERVICE OF PROF. D. HAYES AGNEW, M.D.

Reported by L. B. BALDWIN, M.D.

FEMORAL ANEURISM—DIGITAL COMPRESSION—CURE IN THIRTY-FOUR HOURS.

JOSHUA P., colored, married, æt. 36, male, native of Delaware, and a resident of Philadelphia, was admitted to the hospital December 26, 1874. His own statements were to the effect that he had always enjoyed perfect health, and that he had for many years faithfully performed the duties of his position,—that of a coachman. Six weeks previous to admission, while attaching horses to a wagon, he by accident ran against the iron end of the swingle-tree, striking the inner side of the thigh. He experienced severe, agonizing pain at the point injured for about five minutes; there was

no punctured wound or abrasion of the surface, and he asserts positively that there was no swelling. He continued his duties for seven days, when he complained of severe pain on the inside of the knee. Four days later, or ten days from the accident, he discovered the pulsating tumor for which he now asks admission to the hospital.

Upon making a physical examination of the tumor, the first thing that strikes our attention by mere inspection is the heaving, pulsating character which the tumor possesses. On closer inspection, aided by palpation, we find that it is in the line of the femoral artery; that it pulsates forcibly, the dilatation being equal in all directions at every pulsation, which corresponds with the radial pulse; that it ceases to pulsate and diminishes in size when the artery is pressed upon above the tumor; and that, upon auscultation, is heard the almost characteristic aneurismal murmur or bruit. Its position is on the line of the femoral artery of the right leg, seven and a half inches below Poupart's ligament, which places it below Scarpa's triangle, outside the sartorius muscle, and just above the canal in the adductor magnus. It is the size of a goose-egg. There is no unnatural heat or discoloration in the part. It is fusiform in shape, and evidently due to contusion.

He was presented to the class on January 6, 1875, and the subject of aneurisms and the various methods of treating them considered at some length. The preference was given to digital compression, notwithstanding that our aneurism was fusiform, the one above all others acknowledged to be most difficult to cure by this method.

The patient having been prepared since admission by absolute rest in bed, with the leg elevated to an angle of 45°, restricted diet, and a heart-sedative,—tinctura aconiti radices, grt. v, t. d.,—digital compression was commenced by gentlemen from the Medical Department of the University on January 6, 1875, at 7.40 P.M., and maintained for thirty-four hours. The first twelve hours the artery was only partially controlled, in order to favor the collateral circulation. He bore it without a murmur until 1 o'clock P.M. on the 7th, when he complained of pain, and was given a hypodermic of morphia, gr. ¼.

At 3.30 P.M., Bellingham's compressor was adjusted below the origin of the profunda, and caused so much pain as to make it necessary to remove it at the end of an hour and fifteen minutes. Thirty-five drops of tincture of opium were given during this period.

Digital compression was recommenced, and at 10.30 P.M., or twenty-six hours and fifty minutes from the time pressure was first applied, the pulsation, almost suddenly, entirely ceased. The pressure was continued, however, for seven hours and ten minutes longer, making thirty-four hours in all. The man's condition remained good throughout; there was no marked depression, he slept at times, took nourishment with relish, and, without exception, all the organs of the body performed their various functions satisfactorily and with ease to the patient.

The temperature of the limb and foot remained almost normal during pressure. He was kept at perfect rest until January 16, 1875, when he was discharged from the hospital cured.

INTERNAL USE OF SEA-WATER.—Dr. E. Lisle (*Bulletin Général de Thérap.*, February 15) lauds sea-water as a most valuable remedy in strumous, dyspeptic, and anæmic cases. He has made use of it in bread prepared with fresh brine, and also in a combination of brine and syrup, and brine, rum, and syrup with some flavoring essence.

TRANSLATIONS.

EXTRA-UTERINE PREGNANCY (Dr. J. Alonzo y Rodriguez: *El Anfiteatro Anatómico Español*, Madrid, Spain, August and September, 1875).—The patient was aged 39 years, of medium size, multipara. In July, 1858, one month after parturition, she had a sudden suppression of the lochia and milk, and became quite ill. There was much pain and tenderness in the right iliac region, which was treated as ovaritis. The symptoms were alleviated; but accessions of pain with constitutional disturbance were frequent in the same region. In August, increase in size was noticed; heat and redness appeared, and palpation was exceedingly painful. Alarming symptoms of an adynamia came on. Fluctuation was noticed in the tumor August 26, and a small quantity of pus was evacuated by puncture.

A few days later, a portion of the skin around the opening became gangrenous, and a mass of hair connected with macerated skin and pieces of a foetal skull were discharged. A free discharge was maintained, antiseptics were continued, and quinine, with other tonics, freely administered. For a month and a half pus and pieces of the foetal tissues were discharged, and then the opening partially closed by cicatricial tissue, eighteen centimetres in circumference, situated at the junction of the right iliac and hypogastric regions, but leaving a small fistulous opening from which there was a slight discharge up to 1873; though the patient was the previous four years in excellent health and about the house doing much work. In the latter part of 1873 she became again pregnant, and everything progressed well until the fifth month, when she consulted me for pain in the hypogastrium and sacrum. I found anterior obliquity of the uterus, and ordered an abdominal supporter, which relieved her distress, and she was able to continue her usual avocations. The pregnancy progressed favorably, with very little discomfort, but the last two months she was confined to her bed, owing to the distention and weakness of the ventral walls. At the end of the eighth month the distention of the cicatrix produced sloughing of the skin; but ointments and tonics improved her condition, so that the part soon healed. Soon after this the patient had several attacks of uterine pain simulating labor, which passed away under calmate treatment.

Active labor came on May 21, and a male child, between eight and nine months' development, was expelled, but died four hours later. Immediately after the happy childbirth, the last expulsive pain ruptured the abdominal parietes. The cicatrix was torn through, causing an opening eight centimetres in diameter, through which the greater part of the small intestines had escaped.

I hurriedly replaced them, and had the woman retain them with her hand; shortly afterwards we closed the rent by quilled sutures, passing the needle through all the layers of the abdomen, through the sound skin around the cicatrix, so that the serous surfaces of the peritoneum were brought in contact. A compress, covered with simple cerate, was laid over all, and the holy sacrament administered in view of the dangers of peritonitis, not only from the operation, but also from the exposure and manipulation to which the parts and viscera had been subjected.

The patient's face was pallid, extremities cold, pulse small and feeble. There were slight headache, increased thirst, anorexia, and tendencies to syncope.

She was ordered panada, a drink of barley-water, and a teaspoonful of simple antispasmodic mixture; to keep absolutely quiet upon her back, with the inferior extremities flexed upon the trunk.

At our afternoon visit the skin was of normal temper-

ature, the lochia was flowing scantily, and other symptoms were favorable. Treatment was continued, and belladonna ointment was applied over the abdomen for the after-pains.

The next day all the alarming symptoms of peritonitis had supervened, and thirty-six leeches were applied to the abdomen. The patient went through a long and perilous illness, but was ultimately restored to health.

She has continued well, without any suffering from her previous disaster, up to the present time.

W. H. W.

CONGENITAL ELEPHANTIASIS ARABUM, WITH PLEXIFORM NEUROMA (*Centralblatt*, January 23; from *Arch. für Klin. Chir.*).—The case was that of a man 25 years of age, in whose family the disease was hereditary. At birth the patient had a small tumor on the back, which began to grow from the fifteenth year. At his admission into the hospital this growth sloped down from the neighborhood of the lower dorsal vertebra to the right os ilium, as an upper boundary, and from the ramus of the ischium to a hand-breadth below the trochanter major as a lower boundary, hanging down in a purse-like form to the bend of the knee.

Several partial operations were undertaken for the cure of the tumor, which, however, grew again, and the patient finally died of exhaustion and thrombosis of the middle cerebral artery.

Post-mortem examination showed the anterior branches of the right lumbar plexus filled with or changed into knotty tumors, of which some were observed as far as the spinal canal. Even that part of the sympathetic which was connected with the lumbar plexus was included in these changes. From this point outwards there were cords the size of a crow-quill, with bead-like enlargements which could be followed to the centre of the tumor. Similar appearances were found on the branches of the crural nerve. Section through the tumor showed this growth to be situated between the cutis and the fasciæ, pressing in between the fatty layers, and that these became more and more separated from one another towards the centre of the tumor, finally disappearing.

Fine fissure-like vacuoles or hollows were everywhere observed, which were filled with clear, light, coagulable fluid. Microscopic examination showed an increase in the cells of the adventitia, noticeable in the vessels reaching from the fascia to the adipose layer. These cells were wandering cells, or more frequently embryonal connective-tissue cells, the latter lying more thickly near the convolutions of the sweat-glands. The tumor itself was composed of embryonal connective tissue, which became more compact, retaining always, however, a lamellar wall with small vacuoles or spaces. Injection of these spaces showed that the sebaceous and some sweat-glands were surrounded by sac-like lymphatic sinuses, which emptied into the superficial lymphatic rete of the cutis. The knotty neuroma consisted principally of connective tissue, with more or less numerous medullary nerve-fibres. Near these appeared a decided new growth of non-medullated nerve-fibres, and, finally, in the neuromata, lying near the dura mater itself, ganglionic cells.

X.

ULCERS OF THE LEG IN CONNECTION WITH HEART-AFFECTIONS.—Dr. G. Marcano (*Le Progrès Médical*, January 16), having had under observation a number of patients affected with ulcers of the leg, was led to study the etiology of these affections. His observations have brought him to the conclusion that many so-called simple ulcers are caused by troubles of the circulation. Not only varicose veins, but frequently some alteration of the central organ of circulation, may bring about the same effect.

In illustration of this theory, Dr. Marcano brings forward two cases of simple ulcer of the leg, which after remaining under treatment some time succumbed to some heart-trouble.

In the first of these, the ulcer, though originally attributed to a blow, seemed to depend on the condition of the heart for its varying state of progress. While the cardiac affection, under the influence of hospital treatment, was relieved, the ulcer continued to cicatrize rapidly.

A sudden and severe exacerbation of the former was, however, immediately accompanied by cessation of improvement on the part of the ulcer; the granulations of the latter became pale and flabby, the discharge sanious, and an eczematous condition of the surrounding skin supervened. The case resulted fatally, as did the second case which is recorded by Dr. M., in which all the symptoms were identical, but there was no history of the slightest previous injury to the leg.

From his experience in these and many similar cases, Dr. Marcano concludes that: 1, affections of the heart predispose to ulcers of the leg; they may even cause them; 2, these ulcers, which may be called cardiopathic, present a certain degree of frequency; 3, no relation has been noticed between the ulceration and the symptoms noticed in the heart. The cardiac affection, whatever it may be, seems only to play its etiological part by means of the permanent œdema which it produces in the legs, and which is always observed to precede the ulceration.

X.

DANGERS OF ABSORPTION OF PHENIC ACID.—The carelessness with which non-professional journals take up certain popular recipes is not always without its dangers, and especially since these often come into the hands of children. For instance, there appeared lately in one of the public prints an article upon the poison of vipers, which recommended that carbolic acid should immediately be introduced within the wound, the acid to be mixed with alcohol in the proportion of two to one. Observe the off-hand manner in which a toxic agent is spoken of, as if it were the most inoffensive thing in the world. In order to try the experiment, a cat was selected upon whose skin, denuded of hair alone, a saturated solution of carbolic acid in alcohol, mixed with an equal quantity of water, was rubbed. This produced no effect; but when the same solution was rubbed into a scratch upon the nose two or three times, the animal immediately fell into convulsions, and very shortly succumbed. Prussic acid could not have acted more promptly. The moral of this experiment is obvious. —*L'Abeille Médicale*, No. 3, 1875; from *Revue de Thérap.*

X.

ACTION OF CANTHARIDINE.—The *Tribune Médicale*, No. 339, 1875, contains a note on this subject read before the Société de Biologie, of which the following is an abstract. It has long been believed that cantharidic preparations in general, and cantharidine in particular, have a sort of elective attraction for the genito-urinary organs. To prove, however, that cantharidine introduced into the stomach passes into the blood, and that it passes in sufficient quantity to cause grave lesions, eight-tenths of a grain of cantharides was administered to a healthy dog by the stomach. Reiterated vomiting of white, frothy matter expectorated with difficulty and soon becoming sanguinolent, dilatation of the pupil, tendency to immobility, and stupor, resulted. Under these conditions the crural artery of this dog was made to communicate with that of another, and, soon after, dilatation of the pupil was observed in the second animal. Slight dyspnoea was the only other symptom during life; but, after it had been killed, post-mortem examination showed generalized congestion of the lungs, sub-pleural ecchymoses, together with a number of emphysematous

nodules. Large ecchymoses were also observed on the surface and within the ventricles of the heart, as well as localized apoplectic nodules in the liver, injection of the intestinal mucous membrane, congestion of the cortical renal substance, and injections of the vesical mucous membrane, particularly at the neck. X.

DEEP LIPOMA OF THE ARM.—The *Gazette Médicale de Paris*, January 2, 1875, contains an account of this unusual form of lipoma, which presents a certain amount of interest as well from a diagnostic as from a pathological point of view. The tumor was situated under the biceps, and was attached deeply to the periosteum of the humerus. It was removed by a cruciform incision and careful dissection with the knife and fingers.

The difficulty in diagnosis lay in its close resemblance to a cystic tumor or an abscess, but the exploring trocar settled the question before the operation was attempted. X.

THERAPEUTIC NOTES.

UNCHANGEABLE SOLUTION OF QUINIA FOR HYPO- DERMIC INJECTIONS.—

- R Sulphate of quinia, 15 grains;
- Lactic acid (concentrated), 15 grains;
- Water, sufficient to make 60 minims;
- Bisulphite of sodium, $\frac{1}{2}$ grain.

When the solution of the quinia is perfect, add the bisulphite of sodium, and transfer to a well-corked phial.—*A. P. Sharp, in Proc. Am. Pharm. Assoc., 1874.*

IN PROSTATIC GLEET.—

- R Copaibæ, ℥ii;
- Ess. cinnamomi, ℥xx;
- Mucilaginis, ℥xv;
- Aquæ, f℥i.—M.

Sig.—Four times daily.

IN THE COUGH OF CHRONIC PHTHISIS.—

- R Morphiæ acetat., gr. ii;
- Liquor. atropiæ (B. P.), ℥vi = gr. $\frac{2}{10}$ atropia;
- Acid. hydrocyanic. dil., ℥xxvi;
- Syr. pruni virgin. ad f℥iss.—M.

A measured drachm is to be taken, unmixed with water, on going to bed, and once again during the night if necessary.

PRESCRIPTION OF CUBEBS FOR PHARYNGEAL DIPH- THERIA.—

- R Pulv. cubeb. (fresh), 3x;
- Glycerinæ, 3xviii;
- Mel. despumat., 3viiss;
- Aq. menth., 3iii 3i;
- Gum. tragacanth., gr. xv;
- Tinct. ol. menth. pip., gtt. viii.—M.

Dose for a child, one teaspoonful every hour; the broken doses producing the desired effect without irritating the digestive tract.—*La Tribune Médicale.*

CARMINATIVE MIXTURE FOR YOUNG INFANTS.—

- R Sodii bicarbonat., gr. iss;
- Spirit. ammon. aromat., gtt. ii;
- Glycerinæ, gtt. v;
- Aq. menth. pip., f℥ss.—M.

PILLS OF ALOES AND IPECAC.—

- R Aloes, gr. i;
- Ipecacuanhæ, gr. $\frac{1}{4}$;
- Ext. gentianæ, gr. iss.—M.

Ft. pil. no. i. Dose, one to two pills.

TRANSPARENT TURPENTINE LINIMENT.—The following preparation is so composed that, instead of making the half-dissolved cloudy mixture usually seen where oil of turpentine has been mixed with tinctures, it forms a perfectly clear solution:

- R Ol. terebinth.,
- Tinct. aconit. rad.,
- Spiritus camphoræ, āā 3ii;
- Tinct. iodinii,
- Carbon. bisulph., āā 3i.—M.

This mixture separates very quickly into two layers; but if the following substances are added it becomes perfectly clear:

- Soap, transparent glycerin, in fine shavings, $\frac{3}{4}$ oz.;
- Otto of cedar, 1 $\frac{1}{2}$ oz.
- or otto of cajeput, 1 oz.

Either of these may be used, and if the bisulphide of carbon is deodorized, the liniment is not offensive to the smell.

ADMINISTRATION OF CASTOR-OIL.—M. Potain recommends, as the best method of concealing the unpleasant flavor of castor-oil, to squeeze half an orange into a glass, and pour the oil upon it; then, avoiding all disturbance of the liquids, to squeeze the juice from the other half of the orange carefully over it. The oil, thus enclosed between two layers of orange-juice, can be swallowed without the least perception of its flavor.

LINIMENT FOR SCABIES.—Dr. Clemens gives the following formula:

- R Acid. arsenios., gr. i;
- Potassii carb., gr. xv;
- Spiritus saponis, f℥iii;
- Aquæ, f℥iii.—M.

The liniment to be rubbed twice daily on the part affected. It does not harm the youngest child.

PILLS OF IODIDE OF POTASSIUM.—

- R Potassii iodid., 3iss;
- Pulv. althææ, 3iss;
- Syrupi, q. s.—M.

Ft. pil. no. xii.

ANTI-GASTRALGIC PILLS.—

- R Ext. belladonnæ, gr. vi;
- Quiniæ sulph., 3i.—M.

Ft. in pil. no. xxv.

Sig.—Thrice daily, in the treatment of gastralgia.

PILLS OF ACONITE.—

- R Ext. aconiti, gr. vii;
- Confect. rosæ, q. s.—M.

Ft. in pil. no. xx.

One to two, morning and evening, in the osteocopic pains of syphilis, combined with the usual anti-syphilitic treatment.

METHOD OF ADMINISTERING RAW MEAT.—

- Raw meat, scraped, 3 drachms;
- Pulverized sugar, 12 drachms;
- Claret wine, 6 fluidrachms;
- Tincture of canella, $\frac{1}{2}$ drachm.

BROMIDE OF CALCIUM IN THE NOCTURNAL PAINS OF SYPHILIS.—Dr. Galozzi and Prof. Gamberini have employed the bromide of calcium as a sedative in the nocturnal pains of syphilis, with considerable success. The formula employed by them is the following:

- R Calcis bromid., gr. iv ad ix;
- Aquæ destillat., 3iv;
- Sacch. alb., 3ii.

The dose to be increased by 1 $\frac{1}{2}$ gr. daily.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MARCH 27, 1875.

EDITORIAL.

THE UNIVERSITY OF MICHIGAN.

WE have examined the new calendar of the University of Michigan with mingled satisfaction and disappointment. Under the government of the President, James B. Angell, LL.D., the institution has grown and prospered until in the last year it had eleven hundred and ninety-one students, distributed as follows: four hundred and seventy-six in the Department of Science, Literature, and the Arts, three hundred and seventy in the Medical Department, and three hundred and forty-five in the Law Department. As the Medical Department is the only one in which our readers are especially interested, we shall confine our remarks to it. The position which this department holds is, unfortunately, a peculiar one in this country. As it is endowed, its professors are independent of the students, and the fee for its courses is so small as to be practically nothing. An institution of this character must be either a great blessing or a great curse to the community in which it dwells. The grandest conceivable school of medicine is one whose instruction is as free as air, but whose degree is unattainable except as the result of thorough culture in the science and practical training in the art of medicine,—or, in other words, a school which affords opportunities to rich and poor alike, but makes its diploma valuable because difficult of acquirement. On the other hand, a medical institution which offers free instruction and a diploma of easy attainment comes

at once into competition with the ordinary medical colleges, forces them to lower their fees, and, what is even more successful in obtaining classes, their standard of graduation, and of necessity enters itself upon the race in which the most debauched institution will win. It attracts the ignorant in that it offers them, without cost in money or labor, entrance to a profession which is at least supposed to be honorable and to afford a good livelihood to its votaries. The annual overflow of such a medical college must be even more deadly than that which issues in the spring-time from the average school of the country.

The regents of the University of Michigan have had placed in their hands an enormous power for good or for evil. With sorrow we are forced to acknowledge that in the past they have failed to appreciate their true mission. Smitten seemingly with the madness for huge classes, they have lost forever the opportunity, which for years lay in their grasp, of making the University of Michigan the most famous medical school of the country. So far from their large classes being a glory to them, they are the badge of their shame and failure. It is not the number of its graduates, but their training and their character, which stamp an institution of learning.

Judging from their published catalogues and the graduates who have come East, their standard of graduation has in the past been as low as that of our Eastern schools, or even lower, and their diploma to-day is certainly of less rather than of more value than that of our institutions. We have no hesitation in affirming that in the past the University of Michigan has been a grave injury to the profession. It is probable that the errors of the regents have largely been those of ignorance; not one of the board is fitted by education to appreciate the needs of the profession, and the low standard of medical education which has so long prevailed in the United States has produced a murrain of blindness which affects many even of the leading medical men of the day.

It is very probable that the author of the calendar did not perceive the grim humor of the statement—"The University of Michigan has aimed to elevate the standard of medical attainments, as will appear by consulting the requirements for medical degrees." That it has been a very poor marksman we propose to show by consulting the "requirements for the medical" and other "degrees" as contained in the pamphlet before us.

No profession on earth requires for the proper fulfilment of its duties wider or more thorough culture than does that which we serve. Almost

all the sciences underlie it, and almost all the arts bear tribute to it. A fair knowledge of chemistry, physics, anatomy, physiology, and some acquaintance with the natural sciences, are absolute necessities to him who would master the secrets of clinical medicine and surgery, and beyond these is a vast mass of science- and art-knowledge in regard to the natural history of diseases, their production, pathology, cause, and treatment.

We repeat, no human pursuit calls for a greater culture, as none lays a greater responsibility upon its votary, than does ours. Engineering certainly requires no more, and the necessities of the pharmacist in the way of knowledge are a mere bagatelle to those of the physician. How, then, does the course of instruction prescribed for these professions compare with that ordered for the medical student? In making these comparisons, we want first to dispel a delusion, which every one knows to be such, but which is constantly put forward to cover the absolute nakedness of our system of medical teaching.

We are told everywhere that three years of study with a preceptor is a necessity for graduation in the medical school. It is the year and a half of study in the country, which is supposed to precede the study at the college, that constitutes the delusion of which we speak. The professors in our colleges must know that in the great majority of cases this previous study has no real existence, or has amounted to nothing, so that the men come to the city perfectly ignorant of the most elementary principles of our science. The three years is a mere blind for decency's sake.

What faculty would dare to examine these applicants in the rudiments of medical science, even so far as to test their knowing a femur from the humerus? The period of study commences, in nine cases out of ten, when the candidate joins the college. On this basis let us then compare the requisites for graduating in engineering, in pharmacy, and in medicine, in this university whose aim is "to elevate the standard of medical attainments."

In civil or mining engineering the candidate for admission is examined in the English and French languages, geography, history, mathematics, natural philosophy, botany, zoology, geology, and geometrical drawing. In medicine, if the candidate cannot exhibit "a certificate of graduation from a respectable high school, academy, or college, he shall be examined in the *elementary* branches of an English education." In engineering, after having passed his examination, the student is required to study *four years*. In medicine he must attend *two*

full courses of lectures of *six months* each. "Very fine," some one will say; "but, then, civil engineers deal with questions involving property, doctors with questions involving nothing more valuable than life; and, as people will pay much more cheerfully when their property is concerned, civil engineers can afford to educate themselves, and ought to be fitted for their business." True; but then the University of Michigan aims "to advance medical attainments."

Pharmacy, however, is *not* a more lucrative pursuit than medicine, and, as already stated, is greatly below it in the amount of its underlying science and art. In the Department of Pharmacy in the University of Michigan, the student who desires to enter is examined more widely than in the Department of Medicine, and, after entrance, studies *two full years* instead of two *six months*!

We do not want to be misunderstood in regard to the animus of our editorial. We are not attacking the University of Michigan. Its regents have, to our thinking, failed to see the right and do it; but it is not given to every one to be a reformer, and we freely acknowledge that the institution under discussion is equal to, or even better than, the average American college, in that it has instituted at least the shadow of a preliminary examination.

Is it not time, however, for some one to speak in unmistakable tones, when the foremost educators of the nation self-complacently assert before the world, "Our aim has been to elevate the standard of medical attainments," although they require for their medical degree scarcely a sixth of what they do for their degree in engineering, and barely more than half of what they do from the mere druggist? Is it not pitiful to see, in various parts of our country, leaders in our profession so benumbed and blinded by the poison of habit or self-interest that they wonder why it is that power is slipping so from our grasp and that the profession is losing the respect of the people,—why it is that homœopathy and other forms of quackery so grow, and grow, and grow,—when they themselves are nursing the canker-worm that is eating out our vitality and supremacy?

THE past winter has been a very successful one with our medical schools. The Jefferson Medical College, at their recent commencement, conferred the degree of Doctor of Medicine upon one hundred and seventy men. The class of the University was of course much affected by the confusion incident to the hurried removal at the beginning of the session, as is shown by the fact that the graduating class was only one hundred. The Woman's Medical College conferred the degree upon sixteen women.

REVIEWS AND BOOK NOTICES.

ON FUNCTIONAL DERANGEMENTS OF THE LIVER. Being the Croonian Lectures delivered at the Royal College of Physicians, in March, 1874, by CHARLES MURCHISON, M.D., LL.D., F.R.S., Physician and Lecturer on the Principles and Practice of Medicine, St. Thomas's Hospital, etc. 12mo, pp. xvi., 182. New York, William Wood & Company, 1874.

Although recent physiological investigations have shown that the secretion of bile is far from being the only or most important function of the liver, we permit ourselves still to attach undue weight to it, and to forget the essential part the organ plays in the processes of sanguinification and of disintegration of albuminous matter, neither of which can be interfered with without giving rise to functional derangements quite as marked as those produced by conditions affecting the secretion of bile. Thus, urea and various other nitrogenous bodies are formed under normal circumstances in the liver to be afterwards excreted by the kidneys, but if from any cause this function is arrested, or if the amount of albuminous matter conveyed to the liver is so large that its powers are overtaxed, a less highly oxidized product than urea is the result, and hence the appearance of large quantities of uric acid in the urine. The circulation of this body in the blood gives rise to a variety of symptoms which Dr. Murchison groups together under the name of lithæmia, and which are traceable to the perturbing effects it exercises upon the various systems of organs.

When speaking of the treatment of these functional derangements, Dr. Murchison takes occasion to recommend the use of mercury. While fully endorsing the opinion that mercury does not stimulate the secretion of bile, he is nevertheless convinced that there are good grounds for believing that it exerts a beneficial action in these conditions. Part of this is attributable to the purgative properties it possesses, by which the discharge of bile from the bowels is increased, but in addition to this the author believes that it acts by promoting or in some way influencing the disintegration of albumen. Explain it as we may, there is unquestionably a condition recognized by most practical physicians, in which greater benefit will be derived from the use of occasional or repeated doses of mercurials than from that of any other remedy. There is still, it is true, some difference of opinion on this point, but, as the author remarks, the skepticism of the most doubting physician would be removed should he unfortunately find it necessary to test the truth of this statement in his own person. His testimony is the more valuable from the fact that he was taught to regard mercury as a remedy worse than useless, not only in hepatic disease, but also in syphilis. His convictions have, therefore, been forced upon him by experience, and are in no degree the result of preconceived opinions.

These lectures originally appeared in *The Lancet* and in the *British Medical Journal*; but, being the production of one who is an authority on the subject of which they treat, and being well and agreeably written, we think the publishers have done well in reproducing them in their present attractive form.

J. H. H.

SYPHILITIC LESIONS OF THE OSSEOUS SYSTEM IN INFANTS AND YOUNG CHILDREN. By R. W. TAYLOR, M.D., Surgeon to the New York Dispensary, Department of Venereal and Skin Diseases, Physician to Charity Hospital, New York. 8vo, pp. 179. New York, William Wood & Company.

We have to thank the author for calling the attention of the profession to a subject which up to the present

time has received little or no consideration. Dr. Taylor is the first writer who has ventured to give a complete essay in this department of syphilis, and after a careful reading of the volume we have no hesitation in saying that the work has been well and conscientiously done, the result being one of the most studied and elaborate monographs that we know of. The subject is not an extensive one, but yet possesses many points of interest, all of which Dr. Taylor has succeeded in bringing forward in an attractive manner.

The subject-matter is divided into sections, with appropriate headings; the author's experience, together with that of others which he has collected, the symptoms of the disease, the pathological anatomy, diagnosis, treatment, and other questions, all receiving extended consideration. The work is founded chiefly upon a clinical study of twelve cases, which the author has been so fortunate to meet with in his practice, the details of which are related at length, and make a very valuable feature of the book. They are remarkably well reported, and show a laudable desire on the part of the writer to present their peculiarities in every aspect. A very full description of the lesions themselves, as they occur upon one bone or another, and their relations to diaphysis and epiphysis, is entered into, constituting an important part of the subject. The question as to whether osseous syphilitic lesions follow acquired as well as inherited syphilis is answered in the affirmative, and appears to be proven by two illustrative cases. The pathology is well worked out, and is accompanied by a handsomely executed drawing, showing the condition of the bone as it was found in one of the cases.

Perhaps the most useful section to the practitioner is that which treats of the relation of rickets to syphilis. The author supports the view that there is no connection between these two diseases.

The diagnosis of the osseous swellings of syphilis from those of rachitis, a matter of vast importance, is given exhaustively, and is one of the most valuable chapters upon this topic in all literature.

Regarding the book as a whole, it must be considered as a work of decided value, there being in fact no other thorough exposition of this subject extant. It contains much that is new, and is the production of one who has manifestly given much time and study to research, and whose experience enables him to speak with authority. The publisher has clothed the work very elegantly, the type and paper being exceptionally handsome.

L. A. D.

DENTAL PATHOLOGY AND SURGERY. By S. JAMES A. SALTER, M.B., F.R.S. New York, William Wood & Co.

This book, which was originally published by Longmans, Green & Co., of London, contains nearly four hundred pages, written in a pleasant and comprehensive style, doing credit to the author, who has had a good education in general medicine as well as an extended experience in the specialty of which he treats. Dr. Salter, having had these enlarged opportunities, fully appreciates the extent of some of the maladies directly dependent upon tooth-disease, and how largely the pathology of the teeth is associated with serious morbid changes in contiguous structures. Many of the chapters composing this work have been previously published essays, appearing from time to time in the transactions of societies and in hospital reports, and from this publicity have naturally been winnowed of the extraneous and unimportant matter that is frequently found in original papers.

On the general anatomy of the teeth, including their vascularity and sensibility, the author dissents entirely from the views so generally entertained of the nerves

permeating the dentinal tubuli. He says, "The mode in which the hard tissues of the teeth are supplied with nerves is still an enigma, but that there is some supply is certain on physiological grounds. It does not necessarily follow, however, that the nervous connection between the pulp and the dentine should be by direct radiation in the same course as the tooth-tube structure; it may be diffuse and circuitous, and thus an outlying mass of dentine may still maintain a sentient connection with the pulp, . . . the periosteum sharing in this function, as it does in the nutrition and general vitality of the teeth."

In speaking of the functions of the teeth, a diagram is presented, intended to illustrate, by section, the relation of the tongue to the teeth and palate in the production of the numerous sounds; this, with the description accompanying it, though a novel feature in a treatise on dental pathology and surgery, is of interest and not inappropriate.

In alluding to the oft-repeated assertions of the development of third sets of teeth, the author very wisely expresses doubt as to the correctness of these stories. Impacted and undeveloped teeth are of such frequent occurrence that, with the ignorance of the masses of the normal number of teeth, and their inability to assert positively the number of teeth which have been erupted, with the additional fact that no instance has been recorded within the last three-quarters of a century, it is prudent at least not to give undue credence to statements respecting the presence of third sets of teeth.

In treating of irregularities in the position of the teeth, their cause and remedy, while the subject is well presented, the author advances nothing new. The causes, as he enumerates them, are "congenital and hereditary; the prolonged retention of temporary teeth, accidental mechanical influences, disproportion of the size of the teeth and jaws, faulty development of the jaw-bones." For an original investigator to state that these superficial causes produce certain results will not satisfy his many readers. Should he not look beyond, and discern, if possible, some vital condition as a primary cause? These troublesome and unsightly results are of too frequent occurrence and too invariably accompanied by other characteristics to be passed over so lightly. It is a well-authenticated fact that large jaws with teeth standing alone and wide spaces between them belong usually to a low congenital mental development,—a marked reversion to an inferior order of creation; while a contracted jaw, teeth crowded and irregular in position, are accompanied by a good mental development, and not unfrequently a peculiar tendency or predisposition to what are termed nervous diseases.

The chapters on the congenital defects of tooth-structure and form, and on the cause of dental caries, show the result of much thought and experience, but the student cannot finish the perusal of the one on the cause of caries without a feeling of disappointment that one so competent should quote from Leber and Rottenstein's investigations respecting the leptothrix without either accepting or rejecting their theories,—theories which have been widely promulgated and accepted by some as a correct explanation of the cause of caries, but which doubtless involve debatable ground that will be warmly contested before they can rest undisturbed, the large majority of investigators to-day accepting the presence of the "leptothrix buccalis" in the cavity of decay as one of the results of a condition rather than a primary cause.

The result of Dr. Salter's researches upon the growths on the fangs of the teeth, which he terms odontomes, is probably the most thorough and satisfactory that has ever been published on this subject, and the pathologist and physician, who have often been baffled in their efforts to discern the cause of a case of intense and

protracted neuralgia, will find this chapter especially instructive.

For the ably-written chapter on "Secondary Dentine," with the subdivision of the subject into "Dentine of Repair," "Dentine Excrescence," and "Osteo-Dentine," every dental student will thank him. The development of the first of these (dentine of repair), being so thoroughly a remedial effort of nature, and occurring without occasioning nervous disturbance, is wisely designated from the others.

"The painful eruption of the wisdom-teeth," "alveolar abscess," "abscess of the antrum," and "nervous affections from tooth-disease," are all treated in a clear and concise manner. The practical information given in the ably-written and not too long article on nervous affections arising from abnormal conditions of the teeth, forcibly suggests that a more liberal education for the dental student must ere long be demanded, while to extend the studies of the student in general medicine so that he may have a better appreciation of the cause of a not unfrequent trouble with which he has to deal would certainly be a desideratum. Following these is a full and interesting account of the "phosphorus disease," in which many well-authenticated cases, with their treatment, are narrated.

The other chapters not here specified will all well repay a careful perusal. The book is well printed, the subjects nicely arranged, and finely illustrated with one hundred and thirty-three well-executed wood engravings.

To the student in the special department of dental surgery it is invaluable. To the student of general medicine it supplies an unfortunate deficiency in the curriculum of his studies.

C. N. PEIRCE.

ON THE TREATMENT OF PLEURISY; WITH AN APPENDIX OF CASES SHOWING THE VALUE OF COMBINATIONS OF CROTON OIL, ETHER, AND IODINE AS COUNTER-IRRITANTS IN OTHER DISEASES. By JOHN W. CORSON, M.D., Physician to the Orange Memorial Hospital, etc., etc. New York, Wm. Wood & Co., 1874. Pp. 31. Price, 50 cents.

This very thin volume, scarcely thicker than the silver coin for which it is offered as an equivalent, sets forth the results of observations upon more than five hundred cases of pleurisy, made during a service of several years as physician to the class of "Diseases of the Chest and Throat" in the New York and Eastern Dispensaries. The fatal cases only amounted to one-half of one per cent. The treatment consisted of anodyne diaphoretics, with mustard- and bran-poultices in the early stages, and in the later, of iodide of potassium with tonics, and a "croton-oil paint," composed of "olei croton tigii, 3j; ether. sulphur. fort., 3ij; tinct. iodin., 3v," which (together with a stronger form) is highly and, we incline to believe, deservedly praised.

J. G. R.

ON WINTER COUGH, CATARRH, BRONCHITIS, EMPHYSEMA, ASTHMA. By HORACE DOBELL, M.D. Third Edition. Philadelphia, Lindsay & Blakiston, 1875.

This book, which was evidently printed in England, although nominally published in this country, is well known to all specialists, and should be known by all practitioners, although we confess to a little disposition to revise the old maxim so as to read *parvum in multo*. The manner of treatment certainly is exhaustive, but this very fulness gives it an advantage, so that we commend it heartily to those of our readers who are not already familiar with it. The present differs from the second edition chiefly by the addition of two new chapters, and a "complete index prepared by the best index-maker in London."

SELECTIONS.

SHAMPOOING.—Another example of the tendency that prevails to return to primitive measures in the treatment of disease, whether spontaneous or brought on by accident or injury, was lately noticed in Professor Broca's Ward at the "Hôpital des Cliniques." The case was that of a sprained ankle, in which M. Broca employed shampooing, or, as the French term it, "massage," with the best results. He does not believe in the efficacy of absolute rest in sprains, and attaches greater importance to shampooing than is generally accorded to it by surgeons.

"Primary shampooing," he stated, consisted of pressing or kneading the swollen tissues with the fingers; then of alternately flexing and extending the joints affected. By this pressure and forced motion, the extravasated liquids are dispersed into the subjacent cellular tissue. After the first shampooing, the pain and swelling return, but on the second day, when the operation is repeated, its effects last much longer, the pain is diminished, and after a few days, during which the operation is regularly practised, the pain and oedema disappear completely. "Secondary shampooing" is applicable to cases that had not been treated or imperfectly so in the first instance, and in which the pain, swelling, and inability to move have persisted. In such a case he would begin with gentle frictions, which are to be gradually increased, and to be applied to the most painful parts.

The counter-indication against this mode of treatment consists of acute inflammation of the parts; as in such a case the operation of shampooing would not only be intolerable, but would increase the inflammation. In all cases of sprain the utmost care and attention should be paid, with the view of forming a diagnosis, as it would be unpardonable in any surgeon shampooing a fractured limb, a practice not infrequent among quacks and bone-setters. In case of doubt, better treat the patient upon ordinary principles than to resort to the cruel and unscientific method of shampooing under such circumstances. M. Broca then described the process of the operation. After each sitting he applies a roller steeped in Goulard or some other resolvent lotion, and enjoins rest, absolute or otherwise, according to the nature of the case.—*Irish Hospital Gazette*.

GLEANINGS FROM OUR EXCHANGES.

"THE LEAST SACRIFICE OF PARTS" AS A LEADING PRINCIPLE OF SURGICAL PRACTICE (*The Lancet*, January 23 and 30).—Mr. Thomas Bryant lays down the following propositions:

(1) That in cases of disease or accident no more of the body is to be taken away than the necessities of the case demand.

(2) That to carry out this principle the surgeon may, in *pathological amputations*, fearlessly divide tissues infiltrated with organized inflammatory products, and even cut through the walls of suppurating cavities, or through diseased joints.

(3) That in *accidental surgery* parts irreparably injured are alone to be removed, and no healthy tissues are to be sacrificed in order to perform a recognized and probably a named operation. That to these ends the surgeon ought to utilize even doubtfully viable integument, or even leave a stump to granulate, when by so doing some portions of the shaft of a bone can be left, a joint saved, or amputation above a joint avoided.

He says that observation has taught him that amputations and excisions of joints are often performed for local disease in cases from which the local disease could otherwise be removed, with far less risk to life, with an equal probability of securing a good result, and with the preservation of a limb or joint.

Ten cases are given of neurosis and disease of the bones of the foot and the ankle-joint, illustrating the success which has attended the carrying out of the principle of removing only those parts which are actually diseased, taking away dead bone but leaving all other bone alone, and not sacrificing any bone or joint of the foot for no other reason than that a particular operation should be performed.

Fourteen other cases are detailed of disease and abscess of the knee, ankle, elbow, and shoulder joints, showing that free incision into joints, and the removal of necrosed bone therefrom, are excellent and successful operations.

Both of these measures are less severe than resection in the bulk of cases, and far less severe than amputation, and in a number of instances are also more successful.

A free cut into a suppurating or disorganized joint, whether associated or not with bone-disease, is rarely followed by any other than a good result. When the suppurating process is due to synovial disease, a recovery without further surgical interference may be looked for. When due to local necrosis, the incision helps nature towards the recovery of the cases by expediting the process of exfoliation, and the subsequent removal of the bone by either natural processes or some surgical proceeding. And in still more severe cases the incision gives relief, and in no way tends towards inducing any increase in the mischief.

JABORANDI (*The Lancet*, January 30, 1875).—Dr. Sydney Ringer has recently made thirty-seven careful observations on the action of this drug,—twenty on adults and seventeen on children. In many cases the latter were scarcely at all affected, the pulse was but slightly increased in frequency, there was very little sweating or salivation, and all the symptoms were strikingly slight when compared with the marked effects of jaborandi on adults. In the twenty observations made on eighteen adults, the perspiration in every case but two was most profuse, and in those exceptional instances it was free. It began in about ten minutes. In all the cases but one, the pulse was quickened from twelve to forty beats, the average being twenty beats per minute; the average increased frequency lasting two hours and a half. The temperature fell, during the sweating from $.4^{\circ}$ to 1.4° , the average being $.9^{\circ}$. In no instance were the bowels relaxed; in two-thirds of the cases there was nausea, in one-half sleepiness. These observations prove a marked antagonism between jaborandi and belladonna. Belladonna checks the secretion from the skin, the salivary glands, the mucous membrane of the nose, bronchial tubes, stomach, and intestines, and dilates the pupil and contracts the arterioles: jaborandi, on the other hand, increases enormously the perspiration and saliva, and, in a much less degree, the secretion from the mucous membrane of the nose, the bronchial tubes, and the stomach and intestines. Robin asserts, moreover, that it lowers arterial tension, probably by paralyzing the vaso-motor nerves, and thus causing dilatation of the arterioles. Belladonna excites delirium, whilst jaborandi often produces sleep.

Atropia almost immediately checks the profuse perspiration and salivation caused by jaborandi. Belladonna arrests the secretion of milk, jaborandi decidedly increases it.

These drugs both flush the face and quicken the pulse, but belladonna does so by its paralyzing influence

on the pneumogastric, and, possibly, by stimulating the sympathetic nerves. Jaborandi probably quickens the pulse by dilating the arterioles (belladonna contracts them) and lessening arterial tension, thereby allowing the blood to pass more quickly from the arteries into the veins. Jaborandi locally applied to the eye causes (1) contraction of the pupil; (2) tension of the accommodative apparatus of the eye, with approximation of the nearest and farthest points of distinct vision; (3) amblyopic impairment of vision from diminished sensibility of the retina. These effects, however, do not last long.

THE COOLING PACK (*The Lancet*, January 9, 1875).—Dr. William B. Hunter reports the case of a child, æt. 3 years, in whom severe convulsions occurred during the course of an attack of varicella and threatened life. The following treatment was adopted, the axillary temperature being 104° and the pulse rapid. The patient was laid naked on a dry blanket, a towel slightly wrung out of ice-cold water having first been placed beneath him lengthwise. Another cold wet towel was placed over him, and the ends of the blanket were thrown loosely over all. The head was also kept thoroughly wet with cold water.

On feeling the feet and legs, they were found to be cooling rapidly, and already were almost cold; and as their relation to the head in the balance of the circulation, disturbed so much in the direction of the latter, was considered of the first importance, a cloth soaked in a decoction of mustard and hot water was wrapped round them as far as the knees. In about five minutes the towels were replaced by fresh ones from the ice-cold water, and a sponge from the same was gently squeezed over the head-bandage; and this proceeding was kept up, at similar intervals, for about half an hour, the towel to the front being changed twice for every single change of that to the back. At the end of that time the acute symptoms had considerably abated; rigidity had relaxed; quietness had succeeded restlessness; the pupils became more sensitive, and the eyes followed the light; speech, with some degree of intelligence, returned; and the flushed countenance became more natural in its hue. After changing the cloths as they grew warm, for about two hours, the little patient went to sleep in the pack, and the following morning was well enough to be up and dressed. Dr. Hunter particularly recommends this method of reducing the temperature, on account of the facility of its application and the ease with which unpleasant consequences may be averted. Should the least indication of an impending chill present itself through the cooling process being carried too far, the remedy is immediately at hand, in the shape of a few blankets thrown over the patient as he lies in the towels, and tucked closely around the trunk, extremities, neck, and feet, when the temperature would be found speedily to rise again, and the return of the febrile state at the same time effectually prevented by the profuse perspiration which now pours from the soothed and softened skin. The cooling envelope is now converted into a steaming poultice, and sooths by means of a moist warmth, where before it did so by means of continuous cold. By meeting either extreme with its opposite, the mean is ultimately obtained.

GLEETS.—*The Lancet* of February 13 contains a very interesting and practical clinical lecture upon this subject, by Mr. Berkeley Hill. After speaking of the symptoms of gleet, Mr. Hill goes on to say that, owing to the variety of affections causing it, and the fact that the treatment useful for one is very often of little avail for another, time is saved by ascertaining in the first instance the precise nature of the disease giving rise to the discharge. The most common cause is probably

chronic inflammation at one or more small patches in the urethra, left after acute gonorrhœa has subsided. Less frequently the cause may lie in a relaxed and often irritable condition of the mucous membrane at the prostatic part, and even tenderness of the prostate itself. The latter is known (through quacks) to the public as spermatorrhœa. In order to ascertain the seat of the inflammatory patches, Mr. Hill uses an olivary bougie, graduated upon the stem: the increased tenderness at the points of disease marks their locality. When there is more inflammatory congestion than induration, indicated by acute pain with slight resistance to the bougie, and a white, tolerably thick discharge, Mr. Hill uses an injection of two or three minims of a solution of nitrate of silver (ten to twenty grains to the ounce of water), applied to the diseased patch or patches. This causes increase of the discharge for a few days, and, after keeping the patient quiet for that length of time, weak astringent injections are used for four days, and then the strong application again made. If at the end of a week or so there should be any induration, sounds from No. 10 to 12 and 13 are used, and recovery should be complete within three or four weeks. In more obstinate cases soluble and medicated bougies are used, and the urethrotome recommended in case of stricture. *Prostatic gleet* may be brought about either by extension of gonorrhœal inflammation along the urethra, or by congestion and irritation of a sympathetic kind of the prostatic body. Mr. Hill speaks very earnestly in favor of a regimen rather than medication alone in these last cases, but at the same time advises various internal and local measures as appropriate,—injections, the passage of sounds, etc.

THE INFANTILE UTERUS.—Under this title Dr. W. C. Grigg (*Obstet. Jour. of Great Britain and Ireland*, February, 1875) treats of a peculiar condition of the uterus, not infrequently the cause of sterility. He speaks of three forms, two congenital, of which one is and one is not curable, and a third superinduced as a sequence of parturition at an early age, the latter sometimes known as super-involution of the uterus. Each of these forms is briefly described by Dr. G., as well as the various modes of treatment likely to prove available. The article closes by advising a careful diagnosis, as the prognosis differs greatly in the different varieties.

THE TREATMENT OF PUERPERAL FEVER.—*The Lancet* of January 20 states editorially that in the treatment of puerperal fever we must aim chiefly at preserving or restoring the purity of the blood, by fresh air, by copious disinfecting washings of the vagina or even of the uterus,—as with weak solution of Condyl's fluid; at maintaining strength by nourishing and yet convenient food and stimulants; at relieving local pain by occasional opiates, and by warm poultices, which are invaluable. In nearly all cases it will be found that there is some local inflammation of a low asthenic order, like that of erysipelas, to be met, not by old-fashioned antiphlogistics, but, like erysipelas itself, with tincture of iron associated with quinine. The former may be given in a mixture with spirit of chloroform, while the latter is given in a pill, in doses of two grains every four or six hours. The opium may be very conveniently given in the same pill with the quinine, say in quarter- or half-grain doses, or even more. It seems not only to relieve pain, but to act curatively on local inflammation. Purgatives often give rise to much irritation and disturbance, and in grave cases of blood-poisoning we are only too apt to get diarrhœa. In general, it is better to invite the bowels, if sluggish, to act by an enema than to irritate them by a purgative. In no cases is the thermometer more valuable as a guide to the condition of the patient, or to the action of remedies, than in the various cases of puerperal fever.

INTRAPERITONEAL HÆMATOCELE CURED BY FREE INCISION AND DRAINAGE (*Boston Medical and Surgical Journal*, March 4).—Dr. John Hemans was consulted by a woman 38 years of age for a tumor six or seven inches in diameter, in the left hypogastric region, roundish, not tender, movable, quite elastic, but not distinctly fluctuating, and descending into the pelvis. Uterus normal; could be moved to the right, but not to the left. Seven weeks previously, while at stool, she had been suddenly attacked by a severe pain in the left hypochondriac and iliac regions, followed by chills. The next day she noticed a tumor the size of an egg, and very tender, in this region. Vomiting and chills at intervals up to date of consultation. After etherization, the needle of an aspirator was introduced through the abdominal wall, and about seven ounces of dark reddish fluid withdrawn. The tumor was decided to be of the same nature as that of a retro-uterine hæmatocele. Suppuration in the sac followed. Three days later, the tumor had increased in size, and was very hard. There was pain, and increase of temperature and pulse. Etherized again, and tapped with a common trocar through the vagina; about two pints of dark-brown, bloody, offensive fluid escaped. In a few days the tumor had again enlarged. The same operation was once more performed, the opening enlarged with a knife, a large elastic tube introduced, and drainage established. The sac was washed out daily with warm water. The tube was removed in four days; the discharge gradually became healthy, induration disappeared, and at the date of report only a little inoffensive serous fluid was secreted. No subsequent trouble was experienced.

THE COLD-WATER COIL IN INFLAMMATION OF THE EXTERNAL MALE GENITAL APPARATUS, AND AS AN ANTIPHLOGISTIC AFTER OPERATIONS ON THE PENIS.—Dr. F. N. Otis communicates to the *Medical Record* an account of an apparatus which he names the cold-water coil. It is composed essentially of a piece of rubber tubing one-sixteenth of an inch calibre, and six or seven yards in length. At the middle portion this tubing is coiled upon itself, so that by half a dozen turns or more it presents sufficient capacity to encircle loosely the entire penis or scrotum. By placing one end of this tube in a vessel containing ice-water, elevated above the patient's level, and creating a current through it, the application of cold may be continuously and conveniently made. The coils may be retained in place by a piece of cloth folded back and forth over the coils, and to which they may be stitched. Dr. Otis has found this simple apparatus of essential service in the acute form of gonorrhœa, reducing inflammation and preventing erections. It has also proved useful after the operation of circumcision and that for stricture.

COPAIBA AS A DIURETIC.—*The Practitioner* for February contains a communication from Dr. E. L. Dixon, giving his experience in the use of copaiba in cases of ascites from cirrhosis, heart-disease complicated by œdema pulmonum, and heart-disease with albuminuria, ascites, and anasarca.

In each of these cases the administration of the drug was followed by large increase in the amount of urine secreted, and rapid amelioration of all symptoms. The copaiba was administered in the form of capsules. In one case ten to twenty minims were thus given every night, in the other two cases fifteen to thirty minims were administered night and morning.

BROMHYDRIC ACID (*The Peninsular Journal of Medicine*, February, 1875).—Dr. D. C. Wade, after having prescribed bromhydric acid more than sixty times and in a great variety of cases, believes that it is a powerful alterative, a grateful refrigerant and sedative, and that

it affects the stomach similarly to the other mineral acids, increasing the appetite, aiding digestion, and acting as a general tonic.

MISCELLANY.

At the late meeting of the Medical Society of London, the lecturer, Dr. C. F. Alexander, on account of the presence of Mrs. Garrett Anderson, was forced to address his audience as "Mr. President, Madam, and Gentlemen."

NOTES AND QUERIES.

JEFFERSON MEDICAL COLLEGE, PHILADELPHIA, March 13, 1875.

The following prizes were awarded at the Commencement of the Jefferson Medical College, held 11th of March, 1875.

1. A prize of \$100, by H. C. Lea, Esq., for the best Thesis, to Reinard S. Keelor, of Pennsylvania, with honorable mention of the Theses of Harry R. O'Connor, of Pennsylvania, D. Leonard Pratt, of Pennsylvania, J. L. Gaskins, of Florida, and T. Benton Hill, of Pennsylvania.
2. The Toner Medal, by J. M. Toner, M.D., of Washington, D.C., for the best Thesis based on original investigation, to Charles M. Thompson, of England.
3. A prize of \$50, by the Professor of Surgery, for the best Report of his Surgical Clinic, to Dixon C. Allen, of New Brunswick.
4. A prize of \$50, by the Professor of Obstetrics, for the best paper on the Descriptive and Relative Anatomy of the Gravid Uterus, to Thompson E. Potter, of Missouri, with honorable mention of the papers of Joseph F. Robinson, of Missouri, and A. F. Balmer, of Pennsylvania.
5. A prize of \$50, by the Professor of Practice, for the best Report of Clinical Cases, to Daniel M. Appel, of Pennsylvania, with honorable mention of an Essay by Eugene A. Ward, of Missouri.
6. A prize of \$50, by the Professor of Anatomy, for the best Anatomical Preparation contributed to the Museum, to Daniel M. Appel, of Pennsylvania.
7. A prize of a Pocket Operating Case, of the value of \$25, by the Demonstrator of Anatomy, for the best Dissection in the Anatomical Room, to J. W. Pope, of Pennsylvania.

J. B. BIDDLE, M.D.,
Dean of the Faculty.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MARCH 16, 1875, TO MARCH 22, 1875, INCLUSIVE.

- HEAD, J. F., SURGEON.**—Relieved from duty in Department of Dakota, to proceed to Boston, Mass., and, on arrival, to report by letter to the Surgeon-General. S. O. 44, A. G. O., March 16, 1875.
- HAMMOND, J. F., SURGEON.**—When relieved by Surgeon Moore, to proceed to New York City, and, on arrival, to report by letter to the Surgeon-General. S. O. 44, c. s., A. G. O.
- MOORE, JNO., SURGEON.**—Relieved from duty in New York City, and ordered to report in person to the Commanding General, Department of Texas, for duty as Medical Director. S. O. 44, c. s., A. G. O.
- BILL, J. H., SURGEON.**—In addition to his duties as member of the Army Medical Board, to perform, temporarily, the duties of Attending Surgeon at Headquarters Military Division of the Atlantic. S. O. 44, c. s., A. G. O.
- AZPELL, T. F., ASSISTANT-SURGEON.**—Assigned to temporary duty at Fort Columbus, N. Y. H. S. O. 42, c. s., A. G. O.
- ROSE, GEORGE S., ASSISTANT-SURGEON.**—To report to the Commanding General, Military Division of the Atlantic, for assignment to duty. S. O. 42, c. s., A. G. O.
- STYER, CHARLES, ASSISTANT-SURGEON.**—Granted leave of absence for one month. S. O. 34, Department of the South, March 16, 1875.
- SEMGIG, B. G., ASSISTANT-SURGEON.**—Relieved from duty in Department of California, and ordered to Department of Arizona. S. O. 44, c. s., A. G. O.
- BEALL, GEORGE T., MEDICAL STOREKEEPER.**—Granted leave of absence for fourteen days. S. O. 42, c. s., A. G. O.

SATURDAY, APRIL 3, 1875.

ORIGINAL COMMUNICATIONS.

NECROSIS OF THE TEMPORAL BONE.

BY CHARLES SHAFFNER, M.D.,

Assistant-Surgeon to Eye and Ear Institute, Penna.

THE following case is one of the most interesting that has ever fallen under my care, not only on account of its severity, but also from its stubborn progress and final ending in death. I regret that I must furnish an incomplete history, as the post-mortem examination (which the friends would not permit Dr. Keen to make) would have disclosed the exact amount of destruction of the temporal bone, and the condition of the brain and its membranes.

Sarah D., æt. 47, Irish, widow, monthly nurse, without marked symptoms of struma, presented herself for treatment on October 1, 1874, and gave the following history:

She has been a widow for twelve years, and has a daughter fifteen years of age, suffering with chronic otorrhœa. As long as she can remember she has had a discharge from the left ear, of light color, and most probably muco-purulent in character. She has always had good general health, except the discharge from left ear, accompanied with a diminished amount of hearing on that side. The right ear is now, and has always been, healthy. In June, 1874, while attending a labor case, she slept on the floor near an open window, from which exposure an acute otitis media resulted. She had severe burning pains in the region of left ear, which made her cry out with suffering. The otorrhœa was immediately checked by this acute inflammation. The pain deprived her of sleep. She had severe headache, with jumping and throbbing pains in the left ear, attended with tinnitus compared to the roaring of the sea. There was entire loss of hearing on that side. The general symptoms were fever, vomiting, and anorexia.

In a short time a swelling formed about one-fourth of an inch below and posteriorly to the lobe of the left auricle, which was leeches, giving relief for a time. This swelling soon pointed, when it was lanced, discharging a small amount of bloody pus. A fistule was developed, which still remains.

Her attending surgeon performed paracentesis of the membrana tympani, but this did not give her relief. On August 6 the abscess discharged through the membrana tympani, which caused a diminution of suffering. A pain in her ear varying in severity, with a profuse discharge from the external auditory meatus and the fistule, have continued from that time until I saw her on October 1.

On admission, her condition was as follows: She has burning pain in left temporal region. The left side of the face is swollen, with profuse lachrymation of left eye, and some loss of vision. A stiffness of left temporo-maxillary articulation. A very offensive breath, a furred tongue, no sore throat, but thinks the discharge from the ear enters the throat by the Eustachian tube; a very poor appetite, and inability to eat anything solid from the pain which mastication causes in the ear. She is rather pale and thin, and feels weak. Complaints of pain upon tapping with the finger over the mastoid region, but there is no redness here. A very offensive, profuse, and clear discharge from external auditory meatus, and from fistule under the lobule. The dis-

charge contains a number of small irregular yellowish flakes, something like very small rice-grains macerated a long time in water. There is almost entire loss of membrana tympani. Does not hear a moderately loud-ticking watch, even on strong contact, in left ear, but hears a moderately elevated voice quite distinctly. A small probe passes up the fistule for about two inches upwards and inwards without any difficulty, when dead bone is reached, apparently in the neighborhood of the tympanum. When the ear is washed out with the syringe, the water is driven out through the fistule in a thin stream to a distance of three or four feet, showing a communication with the external auditory canal.

The treatment consisted of iron and quinine, occasional anodyne to ear, and good food in a liquid form. She was ordered to wash the ear out frequently with lukewarm water with a syringe at home, and to keep it as clean as possible. The local treatment was syringing, inflating by Politzer's method, with the application of poultices mixed with poppy-heads or tincture of opium. These measures gave partial relief, and were continued.

On October 3 a small piece of necrosed bone was discharged through the fistule, about three-fourths of an inch long, and very narrow, coming, most probably, from the walls of the tympanum.

On October 20 we discovered a piece of bone working out of the external auditory canal, about one and a fourth inches inside the meatus. It was easily seized with the forceps, but quite a strong force could not remove it. We succeeded on October 28 in getting this away in two small fragments. She always felt much better after the pieces of bone came away.

She continued to visit the Institute, but was gradually losing strength. On November 5 she sent word that she had taken her bed and was very sick. I visited her the next day, and found her suffering with fainting-spells. She had frequent severe rigors, or a general tremor of the whole body, and had to be held by attendants. These were not chills, as she had no feeling of being cold. She did not suffer any pain; had hiccough, nausea, and bilious vomiting. Her stomach retained nothing. There was considerable hebetude, and disinclination to talk or to be disturbed. These symptoms indicated that the inflammation was most probably extending to the brain. At this time three fragments of bone were removed from the meatus. She was placed on quinine, stimulants, good food, and subnitrate of bismuth, which relieved the vomiting. The poultices were continued. She gradually improved, and in four days was about the room again. The probe, very carefully used, showed dead bone in all directions inside the auditory canal and tympanum, and I thought the whole petrous portion of the temporal bone was involved, with some extension to mastoid cells. The discharge was very profuse, and in spite of our supporting treatment she was gradually running down. She soon became very weak and unable to eat. The pain in the ear was very acute at times, and I ordered her to dust in the ear one-eighth of a grain of morph. sulph. occasionally.

Finding her attendants could not continue to care for her, I sent her on November 28 to St. Mary's Hospital, where she fell under the care of Dr. Keen. I visited her two days before her death, which occurred about December 12, and found œdema of the lids had set in. She was in a high fever when I saw her, and said she had chills and fever every day,—most probably hectic. She was perfectly conscious; recognized me, and answered all questions correctly. She at no time while under my observation had convulsions, coma, or paralysis, except slightly, as I thought, of left side of the face, due to facial nerve. Dr. Keen informs me

he made every possible effort to obtain a post-mortem examination, and regrets his failure. This would have demonstrated the exact amount of destruction of the temporal bone, and the damage done to the brain, especially as to the existence of abscess of the brain, which we all suspected to exist, but which the symptoms only faintly indicated.

Remarks.—A case of necrosis of the temporal bone is always one of interest and anxiety to the aural surgeon, especially if the patient is an adult and the disease situated in the petrous portion of the bone, as ours was chiefly. Every surgeon notices in his practice a number of cases of cicatrices and depressions over the mastoid cells, indicating severe disease in early life, frequently as a sequela to scarlatina and the other exanthemata; yet the patient has survived it. Caries of the mastoid, especially in young children, is very often recovered from. "Young children will throw off quite large portions of the bone, and yet come off with their lives, while older persons will usually succumb to one of the many consequences" (Roosa). It is also noticed that the prognosis is influenced by the portion of the bone involved, and necrosis of the middle ear is the most dangerous chiefly on account of such complications as meningitis, cerebral abscess, pyæmia, phlebitis with pleurisy and pneumonia (Tanner), paralysis, and fatal hemorrhage. Gruber, Agnew, and others report the extraction of the whole internal ear, the patient living for years afterwards. Very large masses of bone have been removed at times, and the patient has made a lucky recovery; while, again, the operator has unexpectedly found he has exposed the brain, and with grave results, by removing so large a mass.

The case teaches us that no case of otorrhœa is free from risk, and how careful our patients should be not to expose themselves to cold, especially while sleeping, as our case did. It is also very important not to permit a retention of the discharge, for this has frequently caused necrosis, especially in the mastoid cells, with extension to the brain ending in cerebral abscess. A direct communication usually takes place between the diseased bone and the brain-substance through the meninges.

The symptoms of brain-complication sometimes come on suddenly, with a chill, or convulsion, or again with increased pain followed by paralysis, coma, and death.

Our patient gave us only slight symptoms of brain-trouble, so that we could only suspect cerebral abscess; yet Dr. Roosa says, "In very rare cases there are absolutely no symptoms except those of chronic otorrhœa, until death occurs from cerebral abscess."

The *treatment* of our case was chiefly supporting, combined with the use of anodynes. The discharge should be removed as frequently and thoroughly as possible with the syringe, and the middle ear cleared of pus by Politzer's method. All sequestra should be removed with great care, as both the internal jugular and internal carotid have been opened, causing fatal hemorrhage. Leeches externally, with incisions down to the periosteum, occasionally do good, and even such heroic treatment as the trephine

and actual cautery (Gruber) have been used with benefit.

2042 VINE STREET, PHILADELPHIA.

A CASE OF SUPPOSED FRACTURE OF THE ODONTOID PROCESS, WITH RECOVERY.

BY WHARTON SINKLER, M.D.,

Philadelphia.

THE discussion at the Philadelphia County Medical Society (*Philadelphia Medical Times*, March 13) on Dr. O'Hara's "Case of Injury about the Cervical Vertebra," induces me to detail a case which came under my observation at the Pennsylvania Hospital, while acting as clinical clerk to Dr. J. Forsyth Meigs, through whose kindness I am permitted to report it.

Dr. O'Hara remarked that at first he had considered his patient to have sustained a fracture of the odontoid process, but that the diagnosis had afterwards been abandoned.

"Prof. H. H. Smith, after an examination of the case, thought the odontoid process could not have been broken. No authenticated specimen of such fracture had ever been found; and the few cases reported were from extreme violence."

I have met with several cases in point, where there seems to have been but little doubt that there had been a fracture of this process; in fact, the autopsies clearly revealed separation of the dentiform process from the axis. For instance, there is Dr. Willard Parker's case, quoted by Hamilton.*

The patient, a milkman, was thrown from a carriage upon his head and face. On getting up he complained only of faintness, but the next day he had pain in the back of the head, swelling of the neck, and inability to rotate the head. There was no paralysis. In a few days he had sufficiently recovered to resume his business, but a prominence of the neck just below the occiput and a little to the left of the spine remained.

Five months after the accident he began to complain of numbness in his limbs, and to drag his feet when he walked. Two days later, he died instantly, while sitting in a chair.

At the post-mortem examination the odontoid was found fractured through the base and inclined backwards towards the cord.

Sir Astley Cooper† reports the case of a woman in the Female Wards of St. Thomas's Hospital, who, while sitting up in bed eating her dinner, suddenly fell forward dead. At the autopsy it was discovered that the dentiform process was broken off, and that the head in falling forward had forced the root of the process back against the spinal cord, and thus caused instantaneous death.

Dr. Stephen Smith, of New York, in an elaborate paper on the subject,‡ has collected twenty-three instances of fracture of the odontoid process. One is a case reported by Dr. Bayard (*Canada Medical Journal*, December, 1869):

The patient, a child six years of age, fell five feet, striking on her head and neck. She was unable to move her head without great pain, but there was no swelling or irregularity of the neck. Two months after-

* Fractures and Dislocations.

† Dislocations and Fractures of the Joints, p. 463.

‡ American Journal of the Medical Sciences, October, 1871, p. 378.

wards she had convulsive movements of the arms and legs, followed by paralysis of the whole body below the neck. After remaining in this condition for three months, the patient gradually recovered the power of walking. About two and a half years after the accident a post-pharyngeal abscess formed, from which a bone escaped, and this was decided to be the odontoid process.

I will quote one more case from Dr. Smith, which came under his own observation :

A laborer was admitted to Bellevue Hospital three months after having fallen from a building upon his head. At first he thought his neck was slightly sprained, and continued his work for six weeks. His first symptom of serious trouble was a swelling at the upper part of the neck, which was very painful.

Soon after this, he noticed that the arms were growing weak. During the next three weeks the deformity of the neck increased rapidly, and the head became fixed, with the chin carried to the left side and upwards. The paralysis of motion in the left arm became complete, and the power of the right arm was much impaired; the patient also lost all power in the left leg. Sensation diminished in all the limbs. He had constant headache, and there were frequent severe attacks of dyspnoea. The left arm became oedematous, purple, and cold; there was involuntary action of the bladder and rectum.

The patient died one hundred and sixty days after the injury.

At the *autopsy*, the odontoid process was found to be fractured, and carried forward so as to lie in a nearly horizontal position with the anterior ring of the atlas.

This case is remarkable from the fact that for six weeks after the injury there were no grave symptoms. The fracture of the odontoid must have occurred at the time of the fall, but no displacement can have taken place until some time later, when the swelling upon the neck appeared.

In the following case I do not pretend to say positively that there was fracture of the odontoid process, but the symptoms very closely resembled that injury :

Bernard C., æt. 22 years; single; admitted to the Pennsylvania Hospital May 15, 1872. Soon after coming on duty with Dr. Meigs, on August 1, I was struck by the resemblance between the symptoms of the patient and those in the cases of fracture of the odontoid process reported by Dr. Stephen Smith, to which I have just referred. I obtained the following history :

His general health has never been robust, but he has had no definite ailment except a pain in the left side, which he has had off and on since a child. Has never had syphilis or evidences of scrofula.

On April 1, 1872, while in the act of jumping on a train of cars which were in motion, having left the station about one hundred yards, he lost his footing, and was thrown violently from the car to the ground. He thinks he was struck between the shoulders by the end of the car, but he does not know on what part of his body he fell. He lay unconscious for about two hours, when he recovered himself, and called for help, and was taken home. When moved, he suffered intense pain in the back. There was no external injury to the spine or elsewhere, except a small scalp-wound. Head was flexed strongly, with chin resting on sternum, and was immovable. Both arms were completely paralyzed. There was complete loss of power in the right leg to the knee, but below the knee the paralysis was only partial. No facial palsy; the patient states that he was able to

eat, speak, and whistle with ease. There was slight paralysis of rectum, but none of bladder.

He suffered no pain in spine or head while at rest, but whenever moved the pain was intense. There was acute burning pain in the arms and hands, most severe on the posterior aspect of fore-arms and hands. Sensation was wanting in both arms, and a pin could be stuck deep into the flesh without giving him pain. Sensation in both legs unimpaired.

The only treatment he had was cut and dry cups over the spine.

In a week from the injury, power began to return in the right leg, and he was soon able to move it freely. During the next three weeks no other improvement took place; he remained in bed, appetite was good, and he felt comfortable except when moved. About four weeks after the accident he began to move the fingers of the left hand, and in two weeks more he had all of the movements of the left arm. The right arm remained palsied.

On admission to the hospital, there was a large prominence in the cervical region of spine, not painful on pressure, but somewhat so when the head was moved. Was unable to stand, but had full use of left arm, and could move both legs. Treatment ordered was ext. belladonna, gr. $\frac{1}{12}$, ergot, gr. v, t. d., and Huxham's tincture, a teaspoonful three times daily. This was continued until July 18, when tinct. belladonna, gtt. v, ext. ergot. fld., f3j, t. d., was substituted for the pills.

On August 10, he is able to walk about the ward without the least limp, and uses the left arm for everything. The right arm is powerless. There is a swelling upon the neck just below the occiput. The head is flexed, the chin resting upon the breast, and he can raise it but a short distance. There is no pain in the neck, but he complains of its feeling tired if he remains in the erect position long.

August 29.—Improvement continues; can extend head so that chin is four finger-breadths from sternum, and can rotate head about two inches to either side. Has power of flexion and extension of right fingers and wrist, and can pronate and supinate fore-arm, but all these movements are feeble. Paralysis of arm and shoulder still complete. Walks with ease for a short time, but it soon becomes painful to support the head.

Ordered apparatus to support the head, and faradization of right arm. Under this treatment the patient gained rapidly; the apparatus gave him great comfort, and the right arm improved in power.

On January 10, 1873, just before he was discharged from the hospital, he came to my office. He could use the right arm for everything, and could even write quite neatly. The movements of the head were much more free. There was no difficulty in swallowing, and no swelling could be observed in the posterior wall of the pharynx.

I have endeavored to hear of the patient within the last year, but have failed to find out anything of him.

Of course it may be said that in this case there might have been fracture of any of the upper cervical vertebrae; but I think a characteristic feature of fracture of the odontoid process was the position of the head, and the manner in which the patient would steady the head by holding the chin with the left hand.

Dr. Stephen Smith* says, "If the function of the odontoid process is to poise the head upon the spinal column, we should naturally anticipate that the most important and constant symptoms would be those which show that this support is lost."

Since writing the above, I have had the opportu-

* Loc. cit.

nity, through the courtesy of Prof. D. H. Agnew, of examining a beautiful specimen of fracture through the base of the odontoid process in his possession. The patient lived ten days after the accident which caused the injury, and the lesion was diagnosed before death.

348 SOUTH SIXTEENTH STREET, March 18, 1875.

A CASE OF DIRECT TRANSFUSION.

BY FRANCIS L. HAYNES, M.D.

Reported by JOHN R. HAYNES, M.D.

THE subject of the operation, Mattie E., is 27 years old, and married. Her mother is still living, and is healthy; her father suffered from consumption, but died from cancer; one of her sisters suffers from a very chronic form of phthisis. The patient has always been "delicate," and subject to severe attacks of bronchitis. During two of these attacks (which occurred respectively four and two years since) she expectorated small quantities of blood. She has had several attacks of profuse uterine hemorrhage, and states that she has at times vomited blood, and discharged blood per anum.

In April, 1874, after exposure to cold, she contracted bronchitis, which was followed at varying intervals by profuse hæmoptysis. The quantity of blood lost varied at different times from an ounce to a pint. Repeated careful physical examination revealed the existence of no disease except bronchitis.

The attacks of hæmoptysis were not at all ameliorated by the exhibition internally of ergot, digitalis, or any of the numerous astringents; or by inhalations of solutions of the persalts of iron. Finally, hypodermic injections of ergotine (Bullock & Crenshaw) were employed. These invariably checked the hemorrhage within a few minutes, but did not prevent its return. It was found necessary to increase the dose gradually until gr. xv were given at each injection. On several occasions this was repeated the same day. These injections caused great pain and much local inflammation, which, however, in no instance proceeded to suppuration. To allay the pain, morphia was given hypodermically and (as the patient was peculiarly insusceptible to its action) in large doses (gr. j) immediately after each injection of ergotine. When, as occasionally happened, the attack of hæmoptysis was permitted to pursue its own course, the discharge continued with greater or less copiousness during a period of from ten to thirty-six hours.

The digestion was habitually imperfect; attacks of vomiting occurred nearly every day; the appetite was capricious. The menstrual flow occurred at irregular intervals, as had always been the case. The pulse maintained its usual rate and frequency for quite a length of time, but gradually became weaker and more frequent. A more or less troublesome cough, with muco-purulent expectoration, existed.

September 10, 1874, 10 A.M.—Mrs. E. has had a profuse attack of hemorrhage daily for the last ten days. Pulse 144, weak and flickering; respiration

rapid and gasping; temperature (in axilla) 100°. Face pale, lips blanched, and extremities cold. In short, the *tout ensemble* of symptoms was such as to render the prognosis extremely unfavorable. A physician of great intelligence and experience visited the patient, and emphatically expressed his opinion that "that woman was going to die," and it was almost impossible not to agree with him. As a final resort, it was decided to perform transfusion. A young lady in robust health generously offered to supply the blood.

Operation.—The Aveling syringe was carefully prepared by filling it with an aqueous solution of sodium bicarb. (gr. iii- $\frac{1}{2}$) at 100°. The patient, lying in bed, was well propped up with pillows. The donor sat on a chair by the bedside. The right median basilic vein of the patient and the left of the donor were exposed and nicked, and the canulæ introduced, the one in the donor's vein pointing towards the fingers, that in the patient's vein pointing towards the trunk. Eight ounces of blood were slowly transfused. About two ounces escaped from the donor's vein by the side of the canula, which could not be pushed sufficiently far down the vein because of a change in its direction.

While the injection was going on, the patient became quiet and her lips reddened. Dr. Houghton, who had charge of her pulse, noticed no marked change. When the above-mentioned quantity of blood had been transferred, it was noticed that the donor had grown very pale, and that her pulse was very weak. The apparatus was immediately withdrawn, and compresses placed over the openings in the veins. The donor, who by this time had fainted, was laid on the floor. In a few minutes she regained consciousness, and in a week was as well as ever.

Ten minutes after the operation the patient's pulse was 128, stronger and fuller; temperature 100°; extremities warm.

September 11.—Pulse 122, strong; general condition good.

September 12.—Pulse 120. Slight hæmoptysis, which was readily checked by ergotine.

Notwithstanding four or five slight attacks of hæmoptysis brought on by injudicious exertion, the patient made a good recovery, and in two weeks was able to leave her bed.

March 3, 1875.—Mrs. E. has since the last date enjoyed moderately good health. Notwithstanding the greatest self-neglect and frequent exposure, she has suffered but four attacks of hemorrhage, and very rarely requires medical aid. Physical examination shows no pulmonary disease.

THE PERIOD OF MAXIMUM DEATH-RATE.

BY J. BERENS, M.D.

OF the many paths open to the searching investigation of modern science, there is one which has to a great extent escaped the attention bestowed in other directions, and that, too, when data are so easily obtained, and the results to be derived therefrom so patent as scarcely to elude the most superficial scrutiny. The influence which the time of

day has in determining the favorable or unfavorable issue of disease has only very recently been brought before the medical world in the form of statistics from some foreign hospitals.

Deep-rooted popular prejudices are not often without foundation, and it behooves the physician to yield them all respect, however much at variance they may seem with science.

From time immemorial, whenever the lamp of life has been seen to burn feebly, the friends, and oftentimes the physician, have watched with anxiety and solicitude the period of the day peculiar tradition has marked as critical, and indicated as a point upon the hither side of which lurks the King of Terrors, upon the farther side of which gleams at least a ray of hope.

The "turn of the day" is so often heard in the sick-room, and influences to so great an extent the fears and hopes of anxious friends, that its origin and foundation should no longer be allowed to rest in obscurity.

The following tables, which throw some light upon this subject, are made up from the records of over one thousand deaths which have taken place in the Philadelphia Hospital during the past fifteen months. They are made to show the proportion of deaths which occurred during each period of one, two, three, four, six, and twelve hours in the twenty-four :

Hour.	I.	II.	III.	IV.	V.	VI.	Total.
	In each hour.	In each 2 hours.	In each 3 hours.	In each 4 hours.	In each 6 hours.	In each 12 hours.	
Midnight.							
1 A.M.	40						
2 "	48	88					
3 "	39		127				
4 "	39	76		164			
5 "	59						
6 "	50	109	146		273		
7 "	82						
8 "	65	146		255			
9 "	52		198				
10 "	59	111					
11 "	38						
Noon.	46	84	143	195	341	614	
1 P.M.	45						
2 "	37	82					
3 "	39		121				
4 "	53	92		174			
5 "	32						
6 "	48	80	133		254		
7 "	47						
8 "	35	82		162			
9 "	34		116				
10 "	36	70					
11 "	28						
12 "	25	53	89	123	205	459	1073

From these tables it will be perceived that a marked difference appears between the number of deaths occurring at different periods of the day. Thus, a maximum death-rate of 82 is observed between 6 and 7 A.M., and a minimum of 25 between 11 and 12 P.M. Again, from midnight until 10 o'clock A.M. the general tendency is to increase, while from 10 A.M. throughout the remainder of the cycle there is a decrease. This becomes more marked proportionately as the numbers are grouped into sections comprising larger periods. The sudden rise in the rate, and the subsequent decline

after this rise has attained its maximum, are well shown in columns III. and IV. To make a general summary, the death-rate suddenly rises at midnight, and continues to increase until about 9 A.M., when there follows a more or less regular decline, until the minimum is attained, a little before midnight.

As to the underlying causes of these phenomena, they are still shrouded in obscurity. Among them, however, two things must occupy a prominent position,—nursing and the solar influence.

The fact of the existence of a correlation between vital and physical forces may be considered as established. In treating of this subject, it must be fully recognized that we are dealing with living animals which have nothing new, as regards the elementary forms of matter of which they are composed.

The vital energy required in the evolution of thought is correlated to heat and other natural forces as closely and as truly as the energy expended in striking an anvil with a hammer. There is no essential difference between them, either as to their quality or mutual convertibility. Organic and inorganic are, in their dependence one on the other, so intimately related that any great motive power for the one must, in its relations to the other, occupy a position of vast importance.

This wonderful unity and close interdependence among the physical forces, mechanical motion, heat, light, and electricity, and the correlation undoubtedly existing between them and the purely vital forces, lead irresistibly to the conclusion that there must occur a complete reversion of their mutual play and activities between the time of meridian of one day and that of the next ; for beyond question the sun is the most prominent source of all energy, whether vital or physical.

To return to the tables : it will be observed that the hour in the twenty-four which is marked by the highest death-rate corresponds almost exactly with the time when, taking the average of the year, the sun has been longest below the horizon of this latitude. After the average time when the sun has risen sufficiently above the horizon for its influence to be felt, there begins a tendency in the death-rate to decline until midnight. But this decline continues after the average time of sunset, and even grows more marked towards midnight. This latter point seems to militate against any theory of a solar influence. But the fact should be duly considered that the effects of the sun do not disappear with it, that the patient is generally placed under more favorable circumstances and composing influences which the night brings with it, such as nourishment, arrangement of bedding, and, above all, a cessation of the turmoil, the jars and excitements which inevitably, to a greater or less degree, involve even the best-regulated sick-rooms.

Another matter of quite as much moment as the sun and all the attendant train of forces it evokes and sustains, is the undeniable fact that, however assiduous the attendants on the patient may have been through the night, the vigilance of the watchers relaxes as the day dawns, just at the time when it should be most on the alert. In the many cases when the question between life and death is an even

one, this neglect is fatal, and the waning light expires, when a few drops of stimulus, or the mere rousing of the patient from what is often more lethargy than slumber to administer food or medicine at the appointed hour, would have decided the issue in favor of life. The results arrived at in this paper, meagre as they are, possess no mean significance. The field, though not a broad one, is important, and a few hours spent over hospital registers would amply repay those who have opportunity for such research.

If there is a period in the day when a larger demand is made on the energies of a patient, the time should be known, that at that moment science may step in to stimulate flagging nature, and bear part of the burden under which, with failing strength, she already begins to stagger.

NOTES OF HOSPITAL PRACTICE.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

SERVICE OF H. C. WOOD, JR., M.D.

Reported by WM. MASTIN, M.D., Resident.

EPILEPTIC CONVULSIONS WITH CHOREIC TWITCHINGS—NITRITE OF AMYL BY THE MOUTH.

B. D., æt. 20 years; white; seamstress. At the age of twelve she suffered from severe chorea, which, after running a tedious course of many months, left her with occasional spasmodic twitchings of the different muscles of the body, especially of the left side. Three years later she began to have epileptiform attacks, which were preceded by nausea, swimming of the head, with a sense of suffocation, and accompanied by semi-unconsciousness.

By degrees these increased in severity, until they became well-marked attacks of epileptic convulsions, with unconsciousness, frothing at the mouth, biting the tongue, lividity of the face, etc. As the spasms grew worse they diminished in frequency, and the muscular jerkings became constant and more localized. The twitchings are at present almost exclusively confined to the muscles of the left side of the neck, especially the left trapezius, and those of outer side of left thigh and calf. The trapezius by its rapid contractions throws the head backwards in quick succession, but with no regularity, whilst the muscles of the calf act rhythmically.

She is extremely nervous and hysterical; the least excitement increasing the twitchings, and causing jerkings of other muscles not ordinarily affected.

In the intervals of the attacks of the epileptic convulsions her general health is perfect; but her memory is failing. The ophthalmoscope reveals nothing abnormal. On admission, she was put in a quiet ward, and placed on large doses of potassium bromide, then of arsenic, then of nitrate of silver, etc., but, without benefit. Finally, one drop of nitrite of amyl three times a day was ordered to be given by the mouth, and cautiously increased.

The first dose was given on a small lump of sugar in the morning, about one hour after breakfast. Almost simultaneously with its being swallowed the heart commenced to act violently; the respiration was hurried and labored; she gasped for breath; the face was flushed almost to lividity, and she complained of a fullness and tightness of the head, so that it seemed to her it would burst and her eyes start from their sockets. These symptoms followed each other so quickly that

there was hardly a perceptible interval between them. The pulse was very rapid,—150 in the minute,—but not lessened in force, each beat being full and distinctly felt by the fingers.

The thermometer in the axilla registered 99° Fahr.; but this increase in the temperature was doubtless due to the arterial excitement. The paroxysm lasted about one minute and a half, the disagreeable symptoms passing off rapidly. As they did so, the pulse and temperature fell to their normal position.

No feeling of exhaustion or weakness followed this stage of excitement; but the muscular twitchings, both of the neck and leg, were very much lessened. This quieting of the muscular spasms continued from an hour and a half to two hours, after which the former condition was gradually redeveloped.

The second dose, which was given just before dinner, caused the same symptoms as the first, but the third had no effect whatever; not even the slightest quickening of the pulse was produced.

The one drop was recommenced in the morning, but by degrees, as the system became accustomed to its presence, it lost all influence. Then two drops were given three times daily, each dose producing intense cardiac action and flushed face, and relieving the chorea for the time.

After a few days the larger dose began to lose its power over the jerkings, although the excited action of the heart and other phenomena were still caused by each dose.

A third and fourth time the amount was raised, until two drops were given seven times a day, making fourteen drops in the twelve hours. This quieted her completely, and while it was continued she was almost entirely free from the choreic twitchings; but the benefit was only temporary, for, so soon as one or two doses were omitted, the movements returned with equal severity.

Although the salt was given in such large doses, and continued so long, at no time were there any unpleasant symptoms beyond those already detailed. There was no diminished sensibility in any part of the body, no numbness or tingling complained of.

The amyl salt controlled the local chorea, but in the quantity mentioned did not exempt her from the epileptic attacks; although if given when a spell was about to come on it effectually prevented it.

On two such occasions two drops were exhibited, and she became at once quiet, went to sleep, rested, and next morning awoke, feeling quite well.

When under the full influence of the drug, her menses came on at the expected period. They were perfectly natural in every particular, the flow being well established, but not increased in the least, and lasted the usual time.

The pulse-rate and temperature were taken a number of times during the use of the medicine. Just after a dose the pulse ranged from 140 to 160 per minute, the temperature never exceeding 99½° Fahr.; in the interval between the doses, when not under its immediate influence, both the pulse and temperature were normal.

The urine, which was not increased in quantity, was repeatedly examined by the oxide of copper test for sugar, but never once yielded the faintest trace.

In this condition the patient left the house, thus preventing any further observations in the case.

METACHLORAL.—M. Dujardin-Beaumetz reports that he finds in metachloral a useful substitute for iodoform in the treatment of ulcers, etc. A serious objection to the use of the latter agent is found in its very persistent and insupportable odor. From this objection the metachloral is entirely free.

TRANSLATIONS.

OPERATION FOR DOUBLE HARE-LIP.—Prof. Duploy contributes to the *Bull. Gén. de Thérapeutique* for February 28 an account of a case of double hare-lip complicated by prominence of the intermaxillary bone and division of hard and soft palate, which he relieved by resection of the septum, freshening, and suture of the bones. The patient, a little girl, presented the following appearances. The intermaxillary bone was appended to the extremity of the septum, was quite mobile, and extended in front and obliquely upwards, overlapping in front the line of the maxillary bones by about two centimetres (nearly two-thirds of an inch). It was about thirty-five millimetres broad, and bore on its free edge four small, irregularly arranged incisors belonging to the first dentition. (Dental evolution in the lower incisors had terminated six months previously.) The form of the fleshy tubercle was that of a leaflet of a trefoil attached by its smaller extremity to the nose. Two smaller portions adherent to the maxillary bones were adherent also to the *alæ nasi*. The two borders of the labial divisions widely separated and turned back exteriorly were quite thin at their free border, and became smaller towards the *alæ nasi*. Being in part adherent to the maxillary bones, they could be pulled towards the median line only with difficulty.

On opening the mouth, the separation of the maxillary bones was found much less considerable than the size of the intermaxillary. The two maxillæ were approximated, particularly in front, to such an extent as to thrust back the intermaxillary, leaving an interval between them of only twenty-five millimetres, a circumstance important from an operative point of view. The voice was nasal, the articulation poor, deglutition even of liquids was more easily performed than would be supposed.

The operation was as follows: The fleshy tubercle of the intermaxillary was separated with care, the tracts which were bound to the *alæ nasi* being cut at the same time, while the intermaxillary was supported so that the septum should not be injured; the two external incisors, which were only loosely attached, were removed. The intermaxillary was then pierced with a drill, and a double silver wire introduced, the division of which gave two sutures.

A V-shaped fragment of twelve millimetres was then removed from the base of the septum by means of curved scissors. Considerable hemorrhage occurred at this point in the operation, which, however, was successfully checked.

The intermaxillary could now be pushed back until it rested like a keystone between the other bones. The edges of the intermaxillary, as well as those of the adjoining bones, were then freshened, and the parts joined together by wires introduced through holes drilled for the purpose, the apposition of the parts being very close. The restoration of the soft parts was then accomplished by freshening the edges of the central fleshy tubercle, bringing small flaps over from the lateral portions and retaining them by means of seven twisted sutures, four lateral and three inferior; the latter, intended to unite the small flaps to the inferior border of the central tubercle and to blend their extremities, were used in connection with fine pins.

Finally, in order to prevent deformity of the nasal openings, and particularly to avoid the traction which they might exert upon the soft parts below, a long pin was run through the *alæ* and the naso-labial column, and the sides drawn together by a thread.

The result was satisfactory. Union took place along most of the bony parts, and the union of the tissues of the lip was perfect. The two deciduous central incisors

were replaced by permanent teeth, which were too badly directed for purposes of mastication, but which aided in articulation, improving the voice considerably. The former hideous aspect of the face was removed, and the girl's appearance much improved. X.

THE STATE OF THE PUPIL DURING ANÆSTHESIA.—MM. Budin and Coyne contribute to the *Archives de Physiologie*, No. 1, 1875, a communication on this subject, accompanied by illustrative cases. From their observations and researches they draw the following conclusions:

1. The administration of chloroform causes a series of modifications in the pupil which bear a relation to the state of sensibility.

2. During the period of excitation the pupil is dilated.

3. This period passed, the pupil becomes progressively contracted, remaining sensible to excitations.

4. During the period of profound surgical anæsthesia two phenomena on the part of the pupil are constantly observed: 1, an absolute immobility of this organ; 2, a state of contraction. There is a relation between the absolute insensibility of the subject and the contraction with immobility of the pupil; between the return of sensibility and the dilatation with mobility of this organ.

5. The state of the pupil may, then, from the point of view of sensibility, serve as a guide in the administration of chloroform.

6. Gradual dilatation of the pupil supervening during an operation indicates that anæsthesia is less profound, and that sensibility is returning.

7. During operations of long duration, if it is desired that the patient should be completely insensible the anæsthesia should be so managed that the pupils should remain constantly contracted and immobile.

8. Efforts at vomiting may bring about dilatation of the pupil, cause insensibility to disappear, and bring about awakening; it annihilates in part the effects of the anæsthetic.

9. It is important not to confound true chloroform-anæsthesia with asphyxic anæsthesia; the latter causes different phenomena on the part of the pupil.

10. The condition of the iris, although it may serve as a guide for the direction of anæsthesia, does not indicate the imminence of accidents. The pulse, the respiration, and the general condition of the patient must be carefully watched by the administrator of chloroform. X.

EXPERIMENTAL RESEARCHES UPON THE MODE OF ACTION OF THE MORE COMMON EMETICS.—Dr. H. Chouppé's researches (*Archives de Physiol.*, No. 1, 1875) lead him to the following conclusions:

The mode of action of the more common emetics is not the same for all, and if the phenomena which accompany or precede vomiting are closely inquired into the greatest differences will be observed.

Ipecac and its alkaloid emetine, no matter by what way they may be introduced into the organism, always provoke vomiting by direct irritation of the terminal filaments of the pneumogastrics in the mucous membrane of the stomach. Tartar emetic and antimony have a double action: they may act upon the gastric mucous membrane, but also directly upon the medulla. There are, however, differences between these two medicaments: tartar emetic acts more quickly upon the stomach than upon the medulla; apomorphine more rapidly on the nervous centres than upon the gastric mucous membrane. The best proof of this which can be given is, that the dose of tartar emetic sufficient to cause vomiting when injected by the veins must be larger than when it is introduced by the stomach. With apomorphine, on the contrary, the maximum effect is produced by injection into the general circulation. X.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, APRIL 3, 1875.

EDITORIAL.

ALCOHOL IN PYÆMIA.

IT is a well-assured fact that the best treatment for snake-poisoning is enormous doses of alcohol,—as much brandy or whisky being given as the patient can drink, until some symptoms of intoxication are induced, or the patient is dead or convalescent. Putrid matters introduced into the blood in quantity produce symptoms and pathological changes strikingly similar to those of snake-poisoning, as any one can convince himself by experiments on the lower animals. It is, therefore, not unreasonable to try whether narcotic doses of alcohol might not be of use in pyæmia. Moreover, experiments in the laboratory have shown that it is impossible to induce pyæmic fever in animals narcotized with alcohol, and also that it is more difficult than usual to kill such animals with putrid injections.

We do not know whether commencing pyæmia has ever been treated in the way that is orthodox for rattlesnake-poisoning, but certainly, as pyæmia is at present almost synonymous with death, the following enthusiastic and somewhat egotistical experience of Mrs. Jane Grey Swisshelm in the *Chicago Tribune* is worthy of consideration :

"When I went into the hospital service, in 1863, I was at once confronted with the gangrene, and called publicly for 'Lemons! lemons! lemons!' Soon pyæmia followed, and then I called for 'Whisky! whisky!' Everything I asked for came in abundance; pyæmia treated externally with alcohol and water, friction and heat; internally with milk-punch, eggs, rich broths, cherry

wine, although I have had fifty struck by the premonitory chills in one night.

"Surgeons never interfered with my treatment except when I went to them for advice, and I became so confident of success that I used to say, 'If Death wants to get a man from me, he must send some other messenger than pyæmia, for I do not recognize that creation of unskilled surgeons and incompetent nurses.' Alcohol was the basis of my remedies, and 'we praised the bridge that carried us over.'"

The precepts of Mrs. Swisshelm are strongly supported by a series of papers which commenced to appear some months since in the *Deutsche Klinik* (1874, No. 45, 1875, Nos. 2 and 6). In these Dr. Theodore Clemens, of Frankfort, states that he has seen in private practice, during the last fourteen years, eight cases of pyæmia of a high grade, all of which recovered under the free administration of alcohol. He prefers red wine, of which he gives a bottle a day whenever he fears the development of pyæmia, and, so soon as chills appear, increases this quantity to as much as the patient can be got to drink. In regard to the external use of alcohol, of which Mrs. Swisshelm speaks, our readers will remember the remarkable paper by J. L. Suesseroth which appeared in this journal last year. As the result of some little experience and a good deal of reading, we have come to the conclusion that our country friend was about right, and that of all the various antiseptic dressings yet brought forward, whisky is probably the cheapest and most efficient, as it is the safest. Would it be asking too much of our surgeons if they would try alcohol without and within in almost unlimited quantities in pyæmia?

THE AMERICAN MEDICAL ASSOCIATION.—We have received from the Permanent Secretary a circular concerning the meeting of the Association on the 4th of next May, at Louisville, Ky., and closing as follows:

"Secretaries of State medical societies that have adopted the Code of Ethics are respectfully requested to forward to the undersigned a complete list of the officers, with their post-office addresses, of those county and district medical societies entitled to representation in their respective bodies. This is the only guide for the Committee of Arrangements in determining as to the reception of delegates.

"It will also enable the Permanent Secretary to present a correct report of the medical organizations in fellowship with the Association.

"WM. B. ATKINSON, M.D.,
"Permanent Secretary."

We have also received a communication from Dr. Busey calling attention to the rule requiring that all

papers intended to be read before the sections shall be forwarded to the officers of such sections at least one month *before* the meeting of the Association.

The sections and their committees are as follows :

Practice of Medicine, Materia Medica, and Physiology: Dr. Austin Flint, Sr., New York, N.Y., Chairman; Dr. J. K. Bartlett, Milwaukee, Wis., Secretary.

Obstetrics and Diseases of Women and Children: Dr. W. H. Byford, Chicago, Ill., Chairman; Dr. S. C. Busey, Washington, D.C., Secretary.

Surgery and Anatomy: Dr. E. M. Moore, Rochester, N.Y., Chairman; Dr. T. S. Latimer, Baltimore, Md., Secretary.

State Medicine and Public Hygiene: Dr. H. I. Bowditch, Boston, Mass., Chairman; Dr. H. B. Baker, Lansing, Mich., Secretary.

CONCOURS.—Some years since, Dr. Henry Hartsorne won the professorship at the Philadelphia High School by concours, but the method has not taken root in our soil, the climate apparently not being suited to free contests for position. It is with great pleasure that we note the re-inauguration of the plan by the faculty of the Jefferson Medical College, and we trust that its new life may be a longer one. At the recent spirited concours for the lectureship on physical diagnosis in the summer faculty of the school mentioned, there were four candidates, but Dr. Stanley Smith won the position,—a good deal, we believe, to the surprise of the medical circle especially interested in the event. As none of the competitors had achieved reputation by original research, the method of choice was unexceptionable, and we sincerely congratulate both Dr. Smith and the faculty. We do not, however, believe in the concours entirely: we are doubtful of a system which might place a man in a professorship because he was, as a lecturer, a little better than his opponent, although in other respects much inferior to him. A modified concours, in which the final judgment should be based on the published work of the candidate, his practical skill in the branch, his originality, and his trial-lecture, offers, probably, the best possible mode of selection, unless, as in Germany, there could be a gradual promotion by selection from a professorship in a lower to one in a higher school.

TRICHINÆ, according to a Nordhausen paper, have recently been found, on microscopic examination, for the first time, in the flesh of a wild boar. Hitherto it has been believed that these parasites infested the domestic pig alone.

CORRESPONDENCE.

UNIVERSITY OF STRASBURG, March 1, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—In writing my first communication to your journal I shall select a subject which seems to me of the greatest importance,—namely, the possibility of *nourishment with peptones*.

Since Eberle succeeded in making an artificial digestive fluid from the mucous membrane of the stomach, many varied and careful researches have been published upon gastric digestion. The essential result of these researches goes to show that solid albuminous matter passes out of the stomach in a fluid condition and also altered in its properties. The altered albumen, called by Lehmann "peptone," is soluble in watery fluids, whatever their reaction, and does not become precipitated or otherwise altered by boiling, while other solutions of ordinary albumen, as, for instance, white of egg, coagulate upon boiling, and albumen dissolved in acid or alkaline fluids precipitates when these are neutralized. Funke first observed as a peculiarity of peptone that in a state of solution it possessed the property of diffusion through animal membranes or artificial parchment. This property is possessed in general, according to Graham's well-known researches, by those fluids only which are crystalloid in a solid condition. Peptone, however, is an exception to this rule, as in a solid form it is always amorphous. This diffusibility of peptone is therefore the more important a property, since albuminous matters either do not diffuse at all, or do so only to a slight degree, while we are obliged to believe that they reach the blood normally by diffusion. The absorption of albuminous matters into the blood is believed to occur by their first becoming changed into peptone; this is then absorbed, and after absorption becomes again changed into ordinary albumen. The process of peptone formation appears an important one in gastric digestion, and still more so in its relations to intestinal digestion, when it is considered that the pancreatic juice acts upon albuminous matter in the same way as the gastric juice.

A more accurate study of pancreatic digestion has been rendered possible since the discovery of a method of making artificial pancreatic juice, similar to that by which artificial gastric juice has been made out of the mucous membrane of the stomach. It has been found that in digestion by pancreatic juice a peptone is formed similar in all respects to that produced by the action of gastric juice. The pancreatic secretion, however, is active, whether in acid, neutral, or alkaline solutions, being more powerful under the latter condition; while the gastric juice produces its greatest effect, that is to say, the most rapid solution of albumen, in the presence of acid in the proportion of four parts to the thousand. Since, however, the acid digestive mixture of the stomach becomes altered as to its reaction upon entering the duodenum, the albuminous matters undigested by the gastric juice cease to be acted upon, but must

now be digested by the pancreatic secretion. Between the gastric and the pancreatic digestion, however, there is an essential difference. Gastric digestion is entirely completed by the formation of peptone. But, while the peptone formed by the action of the pancreatic juice upon albuminous materials differs in no respect from the former, certain crystallizable matters are formed from this peptone by longer digestion, as Kuhn has shown, matters which are essentially leucine and tyrosine.

By the further progress of the pancreatic digestion, bodies are formed which are decidedly no longer albuminous, and which, if introduced into the system, will not become such, but will either be excreted or will undergo further decomposition.

The question here arises as to whether peptones become ordinary albumen or are broken up into similar constituents, as in the case of prolonged action of the pancreatic juice.

It is the object of the present article to refer to two works which agree in appearing to solve these problems, though, indeed, I propose subsequently to bring forward other researches upon the purely practical side of the question.

There are certain diseases in which, for very intelligible reasons,—*e.g.*, on account of perfect occlusion of the œsophagus,—nourishment can be administered only by the lower intestine. When such nourishment is supplied by means of albuminous bodies, these play an important part, and it becomes a question of moment how we can best bring about the absorption of this material.

The first and simplest question is, Can the intestine absorb to the least extent unchanged albumen if only this is in a soluble form, as, for instance, white of egg, or is this impossible?

While many experiments upon animals appear to indicate that such absorption does take place, yet all these results are rendered negative, or opposed, at least, by the fact that it is impossible to obtain a portion of normal intestinal mucous membrane in a living body which does not secrete digestive juice. Under these circumstances the albuminous material may easily be changed into peptone before absorption. Even though this is the case, it is necessary, in order to be successful in the attempt to give nourishment by this means, that in practice we should, instead of mere albumen, use a so-called digestive mixture. That is, we must use a mixture of some albuminous body, as, for instance, flesh, with artificial pancreatic juice, in order that the formation of peptone may be more rapid, and, consequently, that absorption may take place more quickly. It is still more simple if the albuminous body is absorbed as a peptone, or if the peptone becomes converted into albumen after absorption it is still more simple to make use of peptone directly, and thus to save the sick body the labor of making the change. From this point of view, the question whether the sick or convalescent should be nourished *per anum* or *per os*, and the purely physiological question whether peptone after absorption becomes

converted into albumen, must approach each other closely.

Although these questions had not been decided experimentally one way or the other, yet Leube some years ago succeeded in nourishing sick persons with peptones in practice. The necessary peptones for this purpose were obtained artificially only with great difficulty, and it was only possible to get the remarkable peculiarities of the albuminous bodies by heating them in a Papin's digester, with water, to a temperature of 212° , in order to dissolve them and convert them into peptone. By acting upon flesh in this manner, Leube procured a preparation which he found of the greatest use in a number of cases.

While these purely practical results in the case of human beings were not contradictory to, but, in fact, in support of, the possibility of the metamorphosis of peptone, it was important to get an exact explanation of the question by extending these researches to animals. Such researches were undertaken almost simultaneously by Plotz, in Buda-Pesth, and Maly, in Innsbruck. The researches of these investigators were, fortunately, supplementary to each other, Plotz having experimented upon the dog, and Maly upon the pigeon. In a dog ten weeks old, and weighing 1302 grammes, Plotz ascertained (*Pflüger's Archiv*, Bd. ix. s. 323) the amount of milk ingested daily, and also the proportion of albumen, fat, and salts contained in the same. After the amount of nourishment necessary to support the animal had been ascertained, an artificial fluid nourishment was prepared, containing similar proportions of peptone, butter freed from albumen, grape sugar, and salts. The animal was fed with this fluid, which was injected into the stomach by the aid of a catheter five or six times a day. The peptone was represented by fibrin digested with gastric juice. While on milk diet, the animal took 520 cm. daily, gaining in three days 33 grammes in weight. One hundred centimetres of the milk contained 9.06 grms. solid matters, including 3.35 grms. albuminous, 2.21 grms. fatty, and 0.47 gm. saline. One hundred centimetres of the artificial food contained 5.0 grms. peptone, 5.0 grms. grape sugar, 3.0 grms. fat, and 1.2 to 1.5 grms. salts. The respective proportions are thus seen to differ considerably in the latter case from those ascertained in the case of the milk, and this difference is most marked as regards the salts. The high proportion of this constituent is connected with the condition of the peptone, and, according to Plotz, could only be diminished with great trouble.

Later, the nourishing fluid was made more concentrated, so that 100 centimetres contained 8 grms. peptone, 8 grms. sugar, and 6 grms. fat. During the eighteen days of the experiment, the dog received 567 grms. peptone, 422 grms. sugar, and 309 grms. fat.

During two days it was attempted to nourish the dog on peptone alone; but the occurrence of vomiting and diarrhœa made it necessary to return to the use of the complete fluid. These disturbances excepted, the dog nourished well during the whole course of the experi-

ments. All the functions appeared to be normally performed, peptone appearing neither in the stools nor in the urine. The weight of the animal rose during the course of the research from 1335 grms. to 1836 grms., an increase of 501 grms.

This increase can, however, only be explained by the supposition that the peptone entirely supplants the albumen as regards all the functions of nutrition.

Before Maly (*Pflüger's Archiv*, Bd. ix, s. 585) attempted any researches upon the nourishment of animals, he wished to make a comparison between the chemical composition of peptone and that of the albuminous matters from which it was formed. To this end he bestowed particular care upon the cleansing of the fibrin the digestion of which was to produce peptone. The peptone also was for the most part freed from its essential contamination of salts, which in Plotz's researches had made itself noticeable in a disturbing manner. The salts belonged to the peptones as a result of the method of their preparation from the nourishing fluid, and were separated by Maly by the aid of diffusion. It appeared that in a mixture of salts and peptones the first diffuse so much more rapidly that a separation of the two may be effected without an appreciable loss of peptone. The elementary analysis of the cleansed fibrin, and of the peptone therefrom derived, resulted in showing so little difference as to the elementary composition of these substances that peptone is not to be looked upon as proceeding from a further chemical decomposition of albumen.

Maly made use of pigeons in his experiments, on account of their cleanly habits and the ease with which they can be fed with measured quantities of nourishment. A pigeon was fed with wheat of a known chemical composition to such an extent as just to maintain the "vital equilibrium;" that is to say, it was managed that the amount of nitrogen taken into the body should precisely equal that which was excreted. The pigeon was then fed with pellets containing known quantities of a mixture of similar composition to that of the usual food, excepting that peptone was substituted for the albuminous matter.

Many carefully conducted experiments upon pigeons in which feeding with wheat was alternated with the administration of peptone pills showed that under the use of the latter the body-weight not only held its own, but increased. This could only occur from the fact that peptone was more readily absorbed by the intestines than albumen. At all events, peptone is an albuminous nourishment for pigeons, or, in other words, is a reconstructible and organizable product of digestion.

The practical conclusions which can be immediately drawn from these experiments are the following:

It seems possible that in case of sickness a certain amount of work in the alteration of albumen may be spared the body by its partial nourishment, at least, per anum. In what manner this may best be accomplished in any given case these physiological researches do not indicate.

DR. E. TIEGEL.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, JANUARY 28, 1875.

THE PRESIDENT, DR. WILLIAM PEPPER, in the chair.

Chylous fluid from a hydrocele.

DR. JAMES TYSON presented a specimen of milk-white chylous fluid, sent to him for examination by Dr. C. H. Mastin, of Mobile, Alabama. Six and a half fluidounces of the fluid were removed by Dr. Mastin, by tapping, from a hydrocele, which he describes "as distinct, and on the front part of the testis, just below where the cord emerges from the gland."

On examination, Dr. Tyson found the fluid alkaline, specific gravity 1015, and highly albuminous, becoming almost solid on application of the tests. Microscopic examination revealed a molecular base, some leucocytes, and a smaller number of oil-drops. The suspended portion was almost completely soluble in ether, and there remained a cream-like fluid on evaporation of the latter.

In the Transactions of the Pathological Society of London, vol. xvi. p. 184, is reported a case referred to by Holmes in his System of Surgery. This fluid was milky from the presence of fatty matter.

Bardeleben gives the analysis of a similar fluid from a hydrocele, reported by Vidal. The fluid resembled a fat emulsion or milk, was without odor, saline in taste, and alkaline in reaction; specific gravity 1010, not coagulable by heat or acetic acid alone, but by the action of both coagulation ensued. After adding chloride of sodium, a clear fluid was obtained by filtration which was also coagulable by heat, by numerous acids, sulphate of copper, and alcohol. Treated with ether, so much fat was dissolved that it was possible to form butter. The presence of sugar was revealed by Trommer's and the yeast test; sodium-chloride and lime were found, but no phosphoric or sulphuric acid.

Vidal called this case *galactocoele*; but Dr. Tyson thought the term *chylous* was at least more suitable for the specimen he presented, since it exhibited all the elements of chyle, including the leucocytes or chyle-corpuscles, of which, however, no mention is made by Vidal.

THE PRESIDENT said that it was an interesting fact that nearly all instances of chylous fluid in serous cavities occurred in the *tunica vaginalis testis*. He was not aware of any peculiar relation between the tunica and the lymphatics which would account for the presence of chyle in this situation and not in other serous sacs. The microscopical and chemical examinations show that it is not the result of any grave inflammatory action. There is something still unexplained in relation to the matter, quite worthy of investigation.

Extensive subcranial extravasation, which complicated a fissured fracture of the skull.

DR. RICHARD A. CLEEMANN presented the specimen, and read the following history:

"Through the courtesy of Dr. Tyson, the pathologist to the Hospital of the University of Pennsylvania, I am enabled to show the Society this specimen of traumatic subcranial blood-clot, from a patient who came under my care before his removal to the hospital.

"The subject of the accident was a sailor, 20 years of age. While coming up the river Delaware in a schooner, at 7 A.M., November 30, 1874, he was struck by a block (a heavy piece of wood bound with iron) attached to the jib-sheets. He was unaware of being unconscious

from the blow, though a fellow-sailor afterwards recalled seeing him on his knees; but he could have been stunned but for a very short period, since the captain of the vessel, his father, who was on the after-part of the deck at the time, did not know till an hour afterwards that any accident had occurred. About 10 A.M. the injured man lay down, complaining of pain in the head and vomiting; and in the afternoon I saw him on the vessel, then attached to the wharf. These symptoms still continued, with a feeling of lightness in the head, but he was perfectly conscious and without paralysis. There was tenderness over the right side of the head anteriorly, and a little fullness was observed, but no depression of bone could be anywhere discovered. Ten grains of calomel were ordered, which were to be followed by a dose of sulphate of magnesium. Perfect quiet was directed, and an unstimulating diet.

"I saw the patient the next day about noon. He was now lying on his left side, curled up on the seat of the cabin, and seemed to be made uncomfortable by any attentions paid to him. His father said he could only occasionally cause him to speak, but he would open his eyes, which he kept closed, when told to do so, and, at my request, turned his head from one side to the other. He had been found in the morning at the side of the vessel, where he had gone to evacuate his bladder, a portion of the urine having wetted the deck. I understood at the time that his bowels had not yet been moved, though afterwards I was told that he had had an involuntary evacuation. I now considered him to be in the condition of 'cerebral irritation,' as described by Mr. Erichsen, and, recognizing the likelihood of subsequent cerebral inflammation, and the disadvantages of his residence on the vessel in that event, it was decided that he be removed to the Hospital of the University of Pennsylvania, about a quarter of a mile distant. While I was at the hospital, whither I went at once to make arrangements for his admission, I was hastily summoned back to the vessel on account of an alarming change in my patient's condition. I found him lying on his back on the floor of the cabin, comatose, and suffering one convulsion after another. These spasms were tetanic in character. Suddenly the lower limbs would be rigidly extended with the feet pointed, while the hands and arms would be stiffened and flexed, and in the severer attacks the muscles of the spine would be affected to the degree of producing marked opisthotonos. The respiratory muscles were also involved, at times to the extent of producing mucous rattling in the trachea, frothing at the mouth, and accumulation of secretion in the nose, these symptoms being followed by an approach to stertor in the breathing, which feature, however, was very transient. Borborygmi were heard in the intestines, but accompanied by no involuntary discharge. The pulse, in the intervals of the convulsions, counted sixty beats in the minute, and was oppressed in character. Under these circumstances I opened a vein in the right arm, and observed with interest that the prick of the lancet was followed by the motion of withdrawal of the limb. The blood spurted freely till ten ounces had been lost, when the vessel collapsed. This measure was undertaken, not in the hope of cutting short the convulsions, but as a temporary resource, with the view of diminishing vascular tension, that the cerebral congestion consequent on the muscular disturbances might do less injury. The pulse was more free afterwards, though the number of beats to the minute was not altered. The hospital ambulance, though momentarily expected, did not, through a misapprehension of the driver, arrive for the patient, who thus remained two hours longer on the vessel. During the five hours the convulsions continued; then the man, who had been lying in folded blankets merely, and in a corner of the overheated

cabin, was placed on a soft bed, exposed to a current of fresh air, when the spasms ceased; which sequence allows the inference that they were reflex in character, excited by his uncomfortable position. Finally, he was carried on a stretcher to the hospital. The journey, though short, was a severe one, for the day was very cold, and the way lay across three vessels floating at different heights, and over undulating and broken ground. Whether from these causes or not, the man was repeatedly convulsed during the transit, so that when he was placed in a bed in the ward his condition seemed far worse than before. His skin was now very hot; face somewhat livid, breathing labored, though not stertorous, and pulse 120. I detected no paralysis of the limbs, but the pupils were widely dilated.

"The case now passed from my care, but I learned that the man died ten hours after admission, his condition becoming worse and worse.

"The necropsy was made by the house-surgeon, the head only being examined. A fissured fracture of the skull first presented itself. This fracture, as I saw it delineated on a prepared skull, extended from near the summit of the frontal bone, on the right side, running not far from and apparently parallel to the coronal suture, which it crossed low down, into the right greater wing of the sphenoid, where it divided into two arms, one of which penetrated the lesser wing of the same side. Higher up a branch had been given off, extending forward through the frontal, and another downwards and backwards into the squamous portion of the temporal bone. Examining the cranial contents, a large blood-clot, five inches in diameter and more than an inch thick, is seen, covering, with the exception of a small portion posteriorly, the whole of the dura mater, which corresponds to the right anterior lobe of the cerebrum. The arachnoid cavity is free from blood; the vessels of the pia mater intact, the cerebrum, except the depression caused by the clot and the post-mortem staining, normal. Removing the clot, the larger vessels beneath are found uninjured, as was to have been expected from the late occurrence of the symptoms of compression.

"This case is in accord with the conclusions of Mr. Callender, that rapid death from coma without paralysis is the usual consequence of effusions about the vertex, but it differs from the general rule in the super-vention of convulsions.* It is interesting to note, however, that in Mr. Callender's cases of extravasation into the brain-substance, the spasms were observed, as a rule, when the lesion, which was accompanied with left-side paralysis, was in the *right anterior lobe* of the cerebrum exterior to the optic thalamus and corpus striatum.†

"It is exceptional that so severe an injury as the one recorded should have been received without appreciable loss of consciousness. That this symptom, when secondarily developed, did not make its appearance till thirty hours after the accident, is to be explained, most probably, by an issue of blood so slow that the brain was for a time able to accommodate itself to the disturbing effects of the extravasation.

"As to the question of the use of the trephine in the treatment, this appears to have been one of the rare instances where its use would have been entirely justifiable. The accurate knowledge of the part struck indicated the probable site of injury, while the slow approach of coma and the absence of paralysis seemed to designate an extravasation without the brain-substance proper.

"The post-mortem examination revealed no contra-indications. The consideration of the measure, how-

* St. Bartholomew's Hospital Reports, vol. iii., 1867.

† Ib., vol. v., 1869.

ever, was deferred on the vessel, on account of the more favorable conditions for the performance of the operation in the hospital; the delay in the transmission there of the patient not being anticipated."

Dr. JAMES TYSON said he was reminded, by Dr. Cleemann's case, of another on which he had made the post-mortem examination, which was striking in its parallelism in some points, while in certain other respects it was essentially different.

The case was that of a gentleman about 60 years of age, much addicted to the use of alcohol, who fell upon the ice, walked several squares to his house, and retired to his room. He was in the habit of remaining in his apartment for days at a time, and a similar course at this time did not attract any attention. At the end of thirty-six hours, however, his room was entered, and he was found unconscious and in a dying condition. He was dead when Prof. F. G. Smith, who was called to attend him, entered the room.

There was total ignorance as to the cause of death, and a post-mortem examination was requested with a view to its determination. On inspecting the body, the fingers were found tightly flexed upon the palms, whence it was inferred that he had died in a convulsion. On removing the calvaria and opening the dura mater, a huge clot was found *beneath* the latter, and covering the whole of the anterior half of the right hemisphere, depressing it decidedly, and extending down beneath the base of the brain. *There was no fracture of any portion of the skull.*

The PRESIDENT asked whether there were any evidences on the scalp or tissues beneath which would indicate that the patient had in falling struck his head with violence. It is not improbable that in cases where the walls of the blood-vessels are much diseased, a spontaneous rupture might occur so as to occasion a clot in that position. Hemorrhage into the arachnoid or sub-arachnoid space is not very rare, and, in a large proportion of the cases where he had himself met with it in adults, had been associated with chronic intemperance. The symptoms which characterize meningeal hemorrhage are quite peculiar, and it is possible that at the moment of the hemorrhage a person should fall, but afterwards be able to rise to his feet and find his way home. It is interesting, therefore, to learn whether any evidence was found of such an injury caused by the fall as might have produced this hemorrhage, either by direct violence or by counter-stroke.

Dr. TYSON said there were no evidences of contusion of any part of the scalp or subjacent tissues.

Dr. CLEEMANN remarked that the case, in connection with his own, illustrated admirably the conditions under which trophining might on the one hand be of service, and on the other clearly useless. Thus, in Dr. Tyson's case the position of the clot beneath the dura mater permitted the blood to pass down beneath the brain, so that even if the seat of hemorrhage was reached by the trephine, the operation would avail nothing. But in his own, the clot being external to the dura mater, and therefore circumscribed, its removal was quite within the range of possibility.

He desired to know of Dr. Tyson whether there was any breach of continuity in the brain-substance, as is usual when convulsions occur in like cases. He thought that the convulsions in his own case were evidently of a reflex nature, caused by the uncomfortable position of the man as he lay in the cabin. He thought the brain was in that condition in which it was exceedingly susceptible to irritation, and that under these circumstances the patient would be thrown into convulsions from comparatively trifling causes. He took much interest in these phenomena of the case, from their resemblance to those of certain cases of puerperal convulsions, in which, the brain being already in a state of irritability

from the presence of serum constituting an œdema, as it were, the slightest external irritation would excite a convulsion of great violence.

Dr. TYSON replied that the brain was evidently compressed in this case, but there was no breach in the integrity of its structure.

Soft cancer (encephaloid) of the kidney and of the lumbar glands(?).

Dr. TYSON also presented a specimen of encephaloid of the kidney, removed from a farmer aged 52 years. The case first came under his observation about eighteen months ago, as one of hæmaturia. The hemorrhage had first occurred in the spring of 1873, but for four years previous there were frequent attacks of lumbar pain, which were at first attributed by the patient and his friends to lumbago. They were, however, periodical, and often of extreme severity, and he had actually once passed a small stone, which, from the description of a highly intelligent person who saw it, would appear to have been a mulberry calculus. With these facts before him, Dr. T. was not slow in deciding that the case was one of impacted calculus, although the blood was copious, and there were sometimes coagula. The urine was, of course, highly albuminous, but a microscopic examination, made in August, 1873, revealed no casts. After he came under observation the hemorrhages remained absent for as much as four weeks at a time, but gradually became more frequent, as did the attacks of lumbar pain, which finally became continuous and extreme. The patient gradually became weaker and lost flesh, notwithstanding supporting treatment. Œdema of the right leg appeared, and subsequently extended to the left, and by Christmas, 1873, he was entirely confined to bed. Dulness was now apparent over the region of the right kidney, and the real nature of the disease was suspected, although before this the presence of incontinence of urine also led to the suspicion that the bladder might be involved, a symptom entirely explained by the condition of the spinal cord found post mortem.

He lingered, requiring the constant use of opiates to subdue the pain, until about October 23, when he died.

The post-mortem examination was made by Dr. Hunsberger, of Blandon, Berks County, Pennsylvania, who kindly forwarded the specimens. They consisted of the bladder, two kidneys, and a portion of the tumor. The former organ appears to be healthy, but the left kidney is enlarged, while the right is converted into a trabecular connective-tissue frame-work, the interstices of which are occupied by the usual brain-like substance of soft cancer. The proper situation of this organ was occupied by a large tumor, extending down to the crest of the ilium and eroding the bodies of three or four lumbar vertebrae. Sections of the portion of the tumor sent were made, and found to present the microscopical characters of encephaloid or soft cancer. Pushed up to this tumor, and lying in contact with the stomach, to which it was adherent, was the right kidney, presenting the characters described.

The lungs and liver were the seats of secondary deposits.

A most interesting question in connection with the case is the relation of the large tumor encroaching upon the vertebrae and the cancer of the kidney. The history of the case would seem to point to the former as primary, but it is much to be regretted that the examination did not determine the exact seat of its incipency.

The PRESIDENT said the specimens recalled a case which he had had the opportunity of watching several years ago, in the person of a young man of healthy family history. The lumbar tumor was on the left side, and to it the kidney was closely attached; but, while its ureter was somewhat compressed, the substance of the

kidney was not actually involved by the disease. In this case the periodical character of the lumbar pain was so marked and so extreme as to lead, during the earlier period of the case, to the suspicion of aneurism, although other symptoms of aneurism were wanting. It, however, ran the same course as Dr. Tyson's case, terminating in paralysis and œdema of the lower extremities. There was no abnormal condition of the urine. The right kidney was healthy; the left was flattened and adherent to the lumbar tumor. Its ureter was constricted by adhesions, and the kidney somewhat sacculated in consequence. The mass proved to be a soft cancer of the vertebral glands. The vertebræ were eroded, and prolongations of the growth had extended through the foramina into the spinal canal, and the spinal cord was compressed and softened in its substance.

It is well known that cancer of the kidney is rare, and that changes in the urine are uncertain and inconstant. He had happened to meet several cases of cancer of the kidney which ran their entire course without marked changes, without hæmaturia, albuminuria, or peculiar cells in the urine. In other cases, again, there is the presence of albumen, more or less characteristic cells are found in the urine, while marked attacks of hæmaturia form a very important symptom.

REVIEWS AND BOOK NOTICES.

LECTURES ON DISEASES OF THE RESPIRATORY ORGANS, HEART, AND KIDNEYS. By ALFRED L. LOOMIS, M.D. New York, William Wood & Co., 1875.

The book before us is from one point of view a good one. It is clear in style, conventional in arrangement, very definite and practical in its teachings,—a valuable book for students and for practitioners of a certain class.

Yet after careful examination we fail to find in its pages adequate reason for its publication,—intrinsic *raison d'être*. Its style, though clear, is inferior to that of many recent writings on kindred subjects; the arrangement of topics, though more or less like that usually adopted, is in no way better, and is open to objections on logical grounds: thus, phthisis, which in all its forms is regarded by the author as inflammatory, is not placed in its proper order among or after inflammatory diseases of the lung-tissue proper, but after pleurisy, and the consideration of a pathological new formation, cancer of the lung, is interposed between pulmonary congestion and pneumonia. The descriptions of diseases are excellent, and show patient clinical study and extensive reading; but the parts on morbid anatomy are far from thorough, and have a gotten-up-for-the-occasion appearance by no means satisfying to the anxious inquirer; there is also a disdain of authority in therapeutics which savors of dogmatism. Indeed, reference to authority does not often divert the author from the thread of his narrative, contrary to our expectations in a volume whose pages are almost, if, indeed, not wholly, guiltless of original observations. True, the name of Dr. Bright appears in connection with diseases of the kidney, and those of Virchow and Dr. Stewart with their classification; yet it seems to us that *Diri* would have been no very inappropriate legend at the foot of the final page. The students to whom this book will be most valuable are those who attend the author's lectures, for in it they have, as the preface tells us, a complete shorthand report, and will thus escape the drudgery of note-taking; those practitioners whose shelves are scantily supplied with modern books on general medicine will find this a clever monograph on the special subjects.

The terms "*croupous*" and "*lobular pneumonia*" are

retained, in spite of their inaccuracy and the fact that the former suggests an analogy to pseudo-membranous croup which is not established, whilst the latter has been a source of dire confusion to several generations of writers on pneumonia.

Hay-asthma is clipped of its outward flourishes in seven lines of large type.

A list of remedies for the sweats of phthisis seems to us incomplete when it fails to include atropia, which, though not well borne for any length of time, may often be given with certainty of success in advanced cases, when other means have lost their power, and when even a temporary relief from this harassing symptom is a great boon to the patient.

A few instances of careless proof-reading meet the eye; such as *nitrate of amyle*, p. 427; the omission of a comma in the third line after the heading Prognosis, p. 101, which gives rise to a startling perversion of the sense; and the calm statement that, in pneumonia, "Among the symptoms which may be regarded as unfavorable is a temperature exceeding 105° F.," p. 159.

To the last the most frisky of physiologists will doubtless at once accede without experimental confirmatory proof.

The mechanical work is worthy of all praise.

J. C. W.

GLEANINGS FROM OUR EXCHANGES.

MEANS FOR RELIEVING CHRONIC PHTHISIS.—Dr. James Little contributes to the *Dublin Journal of Medical Science* for January an article "on the means most generally useful for relieving the cough, sweating, and dyspepsia of chronic phthisis." For the relief of the second condition, five grains of Dover's powder administered at bedtime will check phthisical sweating more frequently than any other remedy. Next to it is atropia or its sulphate, best given in the form of pill $\frac{1}{100}$ to $\frac{1}{80}$ of a grain. To prevent the great discomfort of the damp night-dress, Dr. Little advises a large loose night-dress of fine flannel.

For the relief of cough Dr. L. advises a mixture of morphia, atropia, hydrocyanic acid, and syrup of wild cherry. When the expectoration is very tenacious, this mixture does not suit so well as one containing small doses of iodide of potassium with bicarbonate of sodium, hydrocyanic acid, and compound tincture of chloroform. To this, small doses of tincture of opium may be added. This mixture may be taken at short intervals, and continued until the expectoration becomes easier.

In cases where great distress arises from the pain produced during violent coughing by the stretching of old pleuritic adhesions, the play of the diseased lung may be limited by adhesive straps. Dr. Little has used with success strips of dimity five inches wide, and long enough to extend from sternum to spine. One or more may also be drawn across the shoulder, from the interscapular region behind to the mammary in front. Thus supported, the chest-walls are no longer injured by the concussion of the cough, and the greatest relief follows. Chloral to the amount of ten grains in each dose of an opiate cough-mixture will render the effect more immediate and permit a smaller quantity of opiate to be employed. Chloral lozenges are also useful in the case of consumptives who are still going about. In the dyspepsia of phthisis, where there is simply an utter loss of appetite, the only combination which seems to give relief is that of strychnia with phosphoric or hydrochloric acid. It may be given in infusion of columbo or of orange. When, with loss of appetite, there is a feeling of load after food, a dessertspoonful of pepsin wine, with ten minims of hydrochloric acid in a little water after a meal, usually relieves. In pain, flatulence,

cough, and vomiting after meals, tonics and cod-liver oil must be given up for the time, and a regulated and rather spare diet, together with counter-irritation to the epigastrium, must be employed, together, if necessary, with some of the aperients which act upon the upper part of the intestinal tract and some of the medicines which are good against gastric catarrh.

COLD-POWDERS.—Dr. Beard has for some time been using a "cold-powder," the composition of which is as follows: camphor, five parts; dissolve in ether to the consistence of cream; then add carbonate of ammonium, four parts; opium-powder, one part.

Mix, and keep in tightly-corked bottle. The dose is, of course, regulated by the opium, and ranges between three and ten or fifteen grains. He has been accustomed to prescribe it for his friends by the finger-nailful, or as much as can be put on the finger-nail.

This powder may be taken in a little water just before retiring, by preference, or at any hour of the day, whenever there is a *suspicion of having caught cold*. If need be, a moderate dose may be taken several days in succession.

The advantages of this powder are said by Dr. Beard to be:

1. The taste is agreeable, or at least is not disagreeable. Even the bitterness of the opium is mostly neutralized by the camphor and ammonia. No child objects to it.

2. It is singularly and inexplicably efficacious. He believes it to be more efficient than Dover's powder, and incomparably more agreeable. In some cases it produces gentle perspiration; in others, its effect is not observed.

POISONING BY ACONITE.—At a recent meeting of the New York Pathological Society, Dr. Blake related the case of a lady who had taken, by mistake, internally a drachm each of tincture of aconite and chloroform. In the course of half an hour all the contents of the stomach had been evacuated by the stomach-pump. Within fifteen minutes of the accident, the characteristic symptoms of the poison appeared. She became insensible; pulse and respiration ceased. Life was maintained for three hours by the use of a powerful battery, and by the employment of oxygen gas, mixed with equal parts of air. At the end of three hours the pulse began to be faintly perceptible. The urine was found loaded with albumen, and containing fragments of casts. This was at first supposed to indicate a chronic disease of the kidney, but later nothing abnormal was observed in the urine. The patient recovered. The possibility of the kidney-trouble being merely temporary, and occasioned by the irritating effects of the poison, was strengthened by the fact that the skin was profoundly impressed, there being a static congestion of its surface, and the cuticle peeling off on being rubbed.—*New York Medical Record*.

HYPERPYREXIA IN RHEUMATISM SUCCESSFULLY TREATED BY THE COLD PACK.—Dr. Stewart Lockie reports (*Lancet*, February 13) a case of acute rheumatism under his care, in which the temperature rose to 104° on the tenth day, 103.6° on the eleventh, and 106.8° on the evening of the twelfth. It was then determined to attempt to reduce the temperature by the application of cold. A vessel of water with lumps of ice in it was brought to the side of the bed, water-proof sheeting was placed below the patient, and sheets wrung out of the ice-water were wrapped around the body, the sheets being wrung out every few minutes as they became warm. A teaspoonful of brandy was administered every quarter of an hour. At the end of fifty minutes the temperature had fallen to 99.6°, when she was taken out and put between blankets. She fell asleep soon after, and when she awoke, half an hour

later, the temperature was 97.8°. Two hours later it had fallen to 96°. It then rose, and during the subsequent days of the patient's illness never (excepting once, when for a few hours it attained 104°) rose above 102.2°. No further cold applications were used, and the patient made a good recovery.

FOREIGN BODY IN THE BRONCHUS (Dr. Woolverton: *Boston Medical and Surgical Journal*, March 4).—A sailor, while smoking a short clay pipe as he lay in his hammock in an intoxicated condition, fell to the deck, a distance of five feet, sustaining various contusions. Immediately after the fall he had difficulty of breathing for fifteen or twenty minutes, and, although very drunk, screamed with pain, and put his hand over his sternum. During the next four days he complained of cough which "hurt" him, and tenderness about the inferior angle of the scapula. Mucous râles over left side, but respiration free throughout. On the fourth day he ejected during a violent paroxysm of coughing a piece of clay pipe-stem three-fourths of an inch long. He recovered without untoward symptoms.

MISCELLANY.

HIGH, LOW, JACK, AND THE GAME-O'PATHY.—Who is to decide, and how is it ever to be decided, when doctors disagree? The Jack regulars call all Homœopaths quacks; the High call the Low-dilutionists mongrels. Is it any wonder, then, that the Jacks have all the government and state pickings, while the Homœopaths are left out in the cold to fight among themselves? And yet there is as great a difference between the High and Low potency men as there is between the Low-pathics and the Allopathics. The High are Symptom-atologists; the Low are Pathologists. The High give a dose every one or two weeks, and placebo the case through; the Low give a dose every half-hour or hour, and, if characteristic of the disease, cure their patient quickly.—*The U.S. Medical Investigator* (Homœopathic).

A DOCTOR was called in East Hartford to a man, age 66, who was excessively rheumatical. "How long have you had it?" said the doctor. "Forty years," responded the sufferer. The doctor left without prescribing. We cannot tell how much we should like to see even a partial list of the remedies to which, during his life, our Connecticut martyr has probably resorted. He has carried a roll of brimstone in his left pantaloons pocket; he has carried a bit of magnetized iron in his right ditto; he has floated, so to speak, in pain-killer; he has put his trust in "cam-fire," and likewise in capsicum. Whatsoever things are hot or bracing, or tonic or rubefacient, he has resorted to; to the "king of pain," to the "ready and rapturous relief," to oils, to ointments, to poor man's porous plasters, to red flannel shirts, to galvanic braces, to opodeldoc, to herbs, and roots, and seeds,—to all things which grow or flow, which are dugged from the bowels of the earth, which are extorted from crucibles, which drop from retorts, which are rosy or pale in apothecaries' bottles; to powders, to tinctures, to decoctions, to pills, to essences, to panaceas, and to elixirs; to boluses, and globules, and infinitesimal dilutions; to hot rum and water, to cold gin and

sugar, to brandy plain, to sweats and to starvation, to flesh diet and to fish diet and to fowl diet,—and all in vain.—*Tribune*.

GRADUATES IN MEDICINE.—The graduates in medicine of the nine universities of Prussia, Germany, are compelled by law to present themselves before a "State Board of Medical Examiners" for examination before they can be licensed to practise medicine in that State. This same law exists, and is rigidly enforced, in the other States of the German Empire; likewise in Austria, France, England, and in nearly all of the other prominent countries of the world, with the exception of the United States of America.

The following table shows the result of the examinations in Prussia during the past year, and conveys also an idea how rigid these examinations are, for about twenty-five per cent. of the candidates were rejected; and we might further add that no candidate is allowed to go up for examination unless he can prove by certificates that he has attended at least eight courses of medical lectures,—equivalent to four years' study:

1873-74.

Universities.	No. of Candidates.	Passed.	Rejected.
Berlin,	124	89	35
Bonn,	39	33	6
Breslau,	37	32	5
Göttingen,	34	32	2
Greifswald,	81	61	20
Halle,	63	49	14
Kiel,	21	18	3
Königsberg,	45	25	20
Marburg,	33	30	3
Total,	477	369	108

The sum total of physicians licensed in the whole German Empire for the year 1874 is only 660.

During the same year the innumerable medical colleges of the United States of America graduated three thousand students.

In conclusion, we add, for comparison, the following table:

	1874.	
Country.	No. of Inhabitants.	Practitioners licensed in 1874.
Germany,	42,000,000	660
United States,	40,000,000	3,000

Further comment is unnecessary.—*Canada Lancet*.

FOR CLEANING BRASS.—Finely-rubbed bicarbonate of potassium mixed with twice its bulk of sulphuric acid and an equal quantity of water will clean the dirtiest brass very quickly.

THE Central Middlesex (London) coroner has caused a great excitement by insisting upon an inquest of the late Sir Charles Lyell.

NOTES AND QUERIES.

PORT GIBSON, MISS., March 20, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

I was called, a few days ago, to see a negro girl who was suffering from epileptic fits. She had been delivered three or four weeks before of a fine

healthy child, of the ordinary size, and did well till the attack of the fits. She was only twelve years and four months old at the time of her delivery, is well grown for her age, and, as I learned from her mother, had menstruated only once before conception,—a very remarkable case of early maternity.

R. G. WHARTON.

A STATED meeting of the Northern Medical Association of Philadelphia will be held at their hall, 608 Fairmount Avenue, on Friday evening, April 9, at 8 o'clock.

Subject for discussion, Catarrhal Pneumonia following Collapse of Lung: to be introduced by Dr. Edward R. Stone.

The medical profession are cordially invited.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

THE next conversational meeting will be held at the hall of the College of Physicians, Wednesday, April 14, at 8 o'clock P.M.

Dr. W. B. Atkinson will read a paper on "Chloral."

The medical profession in the city are cordially invited to be present.

OBITUARY.

DIED at Easton, Tuesday, March 16, Dr. CHARLES C. JENNINGS.

Dr. Jennings was born in a small town about twelve miles from Bridgeport, Connecticut, in 1806. At the age of fourteen he began teaching school, and continued in that vocation until he was eighteen, when he commenced the study of medicine at Philadelphia. In 1840 he commenced practice at Riegelsville, Pennsylvania, but in 1850 moved to Easton, where he practised continuously to the time of his death. From 1861 to 1865 he was postmaster of the city.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—The reply which I hereby offer to a communication in your last issue respecting an article which I read before the Philadelphia Medical Society, entitled "A Case of Purpura Hæmorrhagica requiring Transfusion," is simply this. In accordance with a request from the Secretary, I consented to read a paper bearing the above title. Those who were present and heard it read will undoubtedly bear testimony to the fact that the article was given strictly in accordance with the title, and also without referring in the least to credit for operative procedures which did not belong to me. I presume that those who know me will bear testimony that it is not my disposition to arrogate to myself a notoriety based upon the talents or work of others, and in this report of a very interesting case it was my object more to describe the condition requiring the operation of transfusion than the operation itself; judging that the latter would form the subject of a paper by Dr. T. G. Morton, as a report of an additional case to the many upon which he has so successfully operated.

Respectfully,

J. M. BOISNOT.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MARCH 23, 1875, TO MARCH 29, 1875, INCLUSIVE.

GRAY, C. C., SURGEON.—When relieved by Assistant-Surgeon Jackson, assigned to duty as Post-Surgeon at Fort Brown, Texas. S. O. 52, Department of Texas, March 22, 1875.

WHITEHEAD, E., ASSISTANT-SURGEON.—Granted leave of absence for one month on Surgeon's Certificate of Disability. S. O. 52, c. s., Department of Texas.

HOFF, ALEX. H., ASSISTANT-SURGEON.—Relieved from duty at Fort Columbus, New York Harbor, and to take station in New York City during his duty with the Army Medical Board. S. O. 50, A. G. O., March 24, 1875.

DE WITT, C., ASSISTANT-SURGEON.—Granted leave of absence for one month. S. O. 37, Department of the South, March 22, 1875.

ADAIR, G. W., ASSISTANT-SURGEON.—Assigned to temporary duty at Ringgold Barracks, Texas. S. O. 52, c. s., Department of Texas.

JACKSON, D., ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Fort Duncan, Texas. S. O. 52, c. s., Department of Texas.

WIGGIN, A. W., ASSISTANT-SURGEON.—Died at Fort Stevens, Oregon, March 7, 1875.

SATURDAY, APRIL 10, 1875.

ORIGINAL COMMUNICATIONS.

ON THE USE OF ALCOHOL IN THE TREATMENT OF DISEASE.

Read before the Philadelphia County Medical Society, January 27, 1875,

BY J. C. MORRIS, M.D.

IN approaching the consideration of my subject this evening, gentlemen, I feel that perhaps a few remarks may not be inappropriate as to the point of view we are to select, as this will be likely to influence materially the impressions to be derived from the facts we are to examine, and the conclusions we may draw therefrom.

In the first place, then, as physicians, our duty is to acquaint ourselves, as thoroughly as we may be able, with the physiological and pathological effects of the various articles and substances which are in daily use around us or by us, either as food or medicine, or which are capable of becoming either the one or the other; to study and promulgate honestly the truth about them, moved neither by fear nor favor, and freeing ourselves as far as possible from the Hudibrastic accusation of "compounding for sins we are inclined to, by damning those we have no mind to." Truth, simple, full, and entire, is the best antidote for the dangers which too often arise from an imperfect or one-sided view of things.

In the next place, we must remember that we are not only physicians, but *men* who have an interest in society, and a duty to perform towards it. This duty indeed is a double one: to restore health as far as possible to the sick, or to alleviate their sufferings; and, so far as in us lies, to protect and elevate the moral tone of the community in which we may dwell. Such is and always has been the aim of our noble profession, which has been and is honored in proportion to the faithfulness of its members to this aim.

But in connection with the use of alcohol, the questions have frequently been raised of late, Are the medical profession in the habit of prescribing alcoholic drinks and preparations so as to be of benefit to their patients? Does alcohol do good under any circumstances? Do physicians' prescriptions and directions encourage intemperate habits in their patients or the community? Probably there is not one of us who has not been asked, or who has not asked himself, these or similar questions, as we have been called upon to witness the terrible effects of the abuse of alcohol; probably there is not one of us who has not felt at times inclined to proscribe, professionally and socially, the employment of an agent which produces such devastation in our midst. It is not my intention to read a moral essay on the subject; this is neither the time nor the place; but I do feel that it is right and necessary to enunciate clearly and distinctly the proposition that the moral character or tendency of remedies proposed is not and cannot be a matter of indifference to a true and honest physician; he is bound, on the contrary, by

all he holds dear or sacred, to give no advice, even as indirectly as Balaam did to the Moabites, which may endanger or lower the moral tone of his patient or the community; but to help social reform, and intellectual as well as physical progress, in every way in his power.

Let us inquire, then, first, what are the physiological effects of alcohol? second, what are the indications for its employment? third, are there any articles known to us which will substitute it? fourth, should we employ it or not?

1. The medical press of the last ten years has abounded in articles on the physiological effects of alcohol, its effects on the pulse-wave and on temperature, and its value as food or medicine. Those who desire to investigate what has been done will find themselves amply repaid by consulting the papers of Anstie, in *The Practitioner*, Thudichum and Dupré's Treatise on Wines, or H. C. Wood's Therapeutics.

But I do not propose so much to reproduce the thoughts and results of these writers as to record my own observations. The effects of alcohol should be carefully distinguished from that of ænanthic ether, etc., as has been pointed out by Thudichum and others, but is too apt to be forgotten. Nor should the tranquillizing, lethargic effect of hops be omitted in considering the effects of beer and ale. It has occurred to me to be a witness of the striking difference between beer and light wine upon large masses of persons. During the Sängersfest held some years ago in this city, I went with Prof. Bridges to Lemon Hill, and there saw about seven thousand of our German fellow-citizens enjoying themselves of a summer afternoon and paying high court to King Gambrinus. The quantities of lager that flowed were simply enormous; yet all was orderly, decorous. The hilarity was moderate. One American, who had imbibed some whisky before entering, became uproarious and combative, and was taken in charge by the police. A shower of rain brought the open-air festivities to a close. Dr. B. and I took refuge in the doorway of a rolling-mill, past which the whole mass poured itself on its way to the city. Good humor, placid booziness, gradually passing into a lethargic indifference to the inconveniences resulting from the jostling of the crowd, were all that we saw.

Upon another occasion, at the Schützenfest in Frankfort-on-the-Main, in 1862, I saw a larger crowd of persons of the same race, gathered in the immense building erected for their accommodation, listening to the music from the various national bands which had assembled there in friendly rivalry, and drinking freely of light wines which flowed on all sides like water. Hilarity was the order of the day. Dancing, singing, friendly gesticulations, hearty greetings,—all the social side of man brought out in the highest degree. Not one instance of intoxication, as we understand it, did I see. Many were somewhat exhilarated, but this subsided gradually, and gradually the assemblage dispersed, gayly and good-humoredly. How many had headaches and empty pockets to greet them on their return

next day to the work-a-day world, I leave for others to conclude.

Of the maddening effects of alcohol on masses of men on a large scale, I have no personal experience to narrate. But the void may easily be supplied by any one who has witnessed a tavern row or who has read the account of the scenes which occurred in Paris when Louis Napoleon, in order to obtain recruits for the Franco-Prussian war, gave the rein to alcoholic indulgence.

When taken in moderate quantities, alcohol produces the following results. The pulse becomes firmer, fuller, harder; the capillaries are filled with blood, which circulates more rapidly in them; the life-changes and functions of all the organs are performed more energetically. To this succeeds a corresponding period of depression, when the pulse beats frequently but feebly, and the functions are all languidly performed. Between these stages there is an intermediate one of stupor, varying in degree and intensity with the quantity of alcohol taken, its rapidity of absorption, and the susceptibility of the individual. How shall we explain these phenomena? The first stage is undoubtedly the result of the direct stimulation of the vaso-motor nerves and of the cerebro-spinal system. This explains the increased exertions, both mental and physical, the heightened courage of the individual. But the same amount only of blood is circulating as before, only with twice the rapidity. It becomes unfit for the repair of the nerve-centres and the continued evolution of nerve-force; the lungs, though moving more deeply and rapidly than before, fail to rid the blood of the increased carbonic acid, which comes from double tissue-waste upon them, reinforced by the decomposing alcohol itself; and a venous stasis commences, marked by a lethargic state of the individual. Gradually the system frees itself from the accumulation, and then the exhausted nerve-centres must wait till fresh food and time for their repair have restored their powers. To follow the effects of alcohol into the domain of pathology, and show the tendency from often-repeated venous congestion to fatty or other degenerations of kidneys, liver, and heart, to epileptiform disease or cerebral softening, is easy and very tempting; but we are considering the physiological, not the pathological, effects. Nor are we here to consider the moral effects; though I cannot help alluding to one striking difference between alcohol and opium, in the crimes they tend to encourage in their victims. The former will stimulate to acts of brutal violence, such as murder; the latter, to those of cunning, such as forgery, or fraud. The former renders a man a nuisance to society, even more than to himself,—a pariah. The latter makes him a nonentity in society, useless, or perhaps hurtful if he be malicious, but a very torment to himself.

2. The indications for the employment of alcohol may easily be drawn from what has been said, as well as the dangers arising from its injudicious or too prolonged employment. It is more nearly a universal stimulant than any other. Where from any cause the vital powers are depressed, and the functions consequently are defectively performed,—

when the circulation, especially, and the nervous energy are unequally distributed,—there we need an agent capable of rousing them temporarily to proper activity, that the needful roborant virtues of food and rest may have time and opportunity to reinvigorate permanently the system. The latter, food and rest, are the only real tonics we possess. These, with healthy (or as nearly so as possible) performance of function by the various organs of the body, maintain that natural system of exchange of the particles of matter entering into our organization, which we call health and life. All other so-called tonics are really only more or less diffusible stimulants. From this it will appear that there is hardly any severe or long-continued illness in which, at some period or other, the use of alcohol in some form may not be indicated. To be of benefit, it should be so employed as to avoid the latter stages. This may be done by using it in small doses, combined with food, or with some more permanent tonics for the absorption and action of which it prepares the system. Used in this way, it may be, and often is, as will appear from what follows, of the greatest benefit,—a powerful agent for good when properly applied, as well as a most dangerous and terrible agent for evil when wrongfully tampered with or indulged in. This has caused its abandonment by many good and earnest men, who have sought to replace it by other means. Let us examine these.

3. Carbonate of ammonium, turpentine, capsicum, and musk are the principal articles which have been at various times proposed or used instead of alcohol. Of the effects of the latter as a general stimulant I have but little personal knowledge. Judging from what I have seen, I should consider it as a stimulant of the emotional nerve-centres, with a secondary influence upon the vaso-motors. Capsicum acts by its local irritant properties, and may, perhaps, produce a sort of secondary reflex irritative fever. It has been recommended and used as a succedaneum to alcohol, and is supposed by many practitioners to be reliable as such. But experience with it in hospital practice in this city has not confirmed this view. It is of great use in flatulent dyspepsia from atony of the bowels, and in the chronic gastritis of drunkards, rousing the exhausted organ to some attempt to perform its duty. But here its usefulness ends. Turpentine, too, acts as a local stimulant to the tissues with which it is brought into contact, and, from its ready absorption, stimulates the circulation by vaso-motor action, rendering the pulse firmer, harder; it also stimulates the action of the kidneys and lungs. But its action on the nerve-centres is comparatively slight; and hence it fails in arousing the system generally to increased activity. The same may be said of carbonate of ammonium and of aromatic spirits of ammonia. These have the property of producing arterial excitement probably from the direct irritation of the tissues with which they come in contact. They are useful as adjuvants,—the former especially when the respiration is embarrassed,—but, from their want of direct action on the cerebro-spinal nervous system, cannot take the place of alcohol. We therefore come to

the consideration of the fourth question : whether, knowing and acknowledging its dangers, we should employ alcohol as a remedy? And, if so, how and when should we give it?

The same argument as to dangerousness applies to other agencies without which civilized life has never been found to exist. Like fire, alcohol has been shown to be "a good servant, but a bad master." In illustration of its value I adduce the following statistics, taken from the records of the Protestant Episcopal Hospital in this city. It occurred to me that, by comparing (if they could be obtained) the results of the treatment of some one disease under similar circumstances by practitioners of similar views generally, but differing in this respect, an opinion might be based upon the facts presented. Typhoid fever is above all others a disease in which good nursing and care, little medicine, and a supporting treatment are required. I therefore requested Dr. S. R. Knight, the superintendent of the hospital, to furnish me an abstract of all the cases of typhoid fever treated by three physicians whose views on the use of alcohol varied as follows: Dr. A. prescribed it sparingly (say f℥xii to f℥xvj of milk-punch — one-fourth whisky) daily; Dr. B. from f℥xvj to f℥xxiv; Dr. C. from f℥xxiv to f℥xlvi. I need not say the result surprised me.

Table of Cases of Typhoid Fever treated at the Protestant Episcopal Hospital; their duration and results.

PHYSICIAN.	YEARS.	TOTAL.	RECOVERED.	DIED.	DAYS IN HOSPITAL.	REMARKS.
A.	1864-1872	65	48	17	34½	Three were moribund on admission; died in less than forty-eight hours. One surgical case, fatal, with typhoid as complication.
B.	1864-1872	56	46	10	35	
C.	1864-1868	26	25	1	39½	

Of the 65 cases admitted under Dr. A., one died in a few hours, and two more in from twenty-four to forty-eight hours; these may be regarded as moribund on admission, and the figures would then show a mortality of 14 in 62 cases (1 in 4½), or more than 22 per cent. If we throw out also the one in which typhoid fever showed itself during the treatment of a fractured arm from railroad-injury, and proved fatal, and which, as far as I can ascertain, was never actually under the charge of Dr. B., the figures would give 9 deaths in 55 cases (1 in 6), or more than 16 per cent. The result of only 1 death in 26 cases under the charge of Dr. C., giving a mortality of less than four per cent., is well calculated to attract our closest scrutiny. The disease seems to have been of a severe, malignant type in 1864, and also, though in a less degree, in 1870-1872; and the figures for Dr. C. (who was not then connected with the institution) might have modified the total percentage somewhat if they had embraced those years. On turning to Dr. Wood's Practice of Medicine, we find that the mortality has varied from 1 in 3½ to 1 in 25 in different years in the Massachusetts General Hospital; nay,

from November, 1836, to November, 1838, there were 55 cases without one death. But all this will not explain away the facts given above, and I find myself forced to the conclusion that the free exhibition of alcohol is of decided advantage in the treatment of typhoid fever. And in all similar conditions of prostration of vital forces we must have recourse to it. The particular form under which we may administer it will vary according to the collateral effects which may be desirable. Thus, should it be desirable to quiet an over-sensitive nervous system, to invigorate digestion and increase fatty deposit, the malt liquors will answer our purpose. Should we on the other hand desire rather to stimulate the cerebro-spinal system and quicken digestion, we will find the lighter wines more useful. In these the ænanthic ethers produce a large proportion of their effect. What this is may be judged of from the effect of nitrite of amyl, an analogous substance, and one that may be added, in very small quantity, to a light wine of low grade, with good results. The extremely minute proportion of ænanthic ether present in natural wine renders it necessary to use this mode of illustrating its activity. The resemblance between the effects is very close. If, on the other hand, an equalization of the circulation and a general stimulation be our aim, the heavier wines, whisky, brandy, gin, or rum will have to be resorted to. The former (when free from fusel oil, which acts as a violent cerebral stimulant and irritant) is the best form of alcohol for administration. It should be made from rye or wheat, not from potatoes, barley, or corn. If an astringent influence on the bowels is desired, brandy among the liquors, and port among the wines, will be preferred; the latter also in cases of debility from hemorrhagic tendency. If a laxative, rum; if a diuretic, gin among liquors, or hock among wines. American wines are, many of them, good of their class, but time and experience in their production in our climate are still needed to enable the manufacturers to rid them of a certain roughness and earthiness, instead of masking these disagreeable qualities by the introduction of sugar. Speaking generally, the less sugar a wine contains the better is it adapted for medicinal employment. In the fermentation of grape-juice, alcohol is produced from the sugar present until the latter is exhausted or a certain percentage of alcohol is formed; if less sugar is present than is required for this percentage, acetous fermentation takes the place of the alcoholic; if more, the wine continues to "improve" by the slow development of ænanthic ether, etc., in consequence of a different form of fermentation; this is analogous with the slow fermentation of lager beer, instead of the ordinary brewing of ale. As long as the sugar lasts this process may continue, until the wine becomes "ripe;" after this it deteriorates, tends to undergo acetous fermentation, and is unfit for use.

Three things should ever be borne in mind in the administration of alcohol, except in cases of shock or hemorrhage: 1. It should be given in small, definite quantities, at intervals of three or four hours generally, so as to produce repeatedly the primary

effects, and avoid the second and third stages of its action. 2. It should always, if possible, be accompanied by food, which may thus aid in the permanent invigoration of the patient. 3. It should be withdrawn gradually, but steadily, as the patient regains strength, and no patient should be left to the continued use of it after recovery. While the disease or debility continues, large quantities will often be necessary, but as the powers of the system are restored the desire for it will lessen and disappear, unless an unnatural appetite or craving is awakened. It has been my experience that patients generally readily and gladly assent to its withdrawal as to that of other medicines, when the need for it has ceased; and, after a practice of more than twenty years, I have yet to have upon my conscience the knowledge that one fellow-being has fallen into habits of intemperance (so far as I know) from my prescription.

I would add one hint: when a patient complains of being heated, flushed, rendered uncomfortable, by the administration of alcohol, revise your diagnosis. It may be that you are administering it in an unsuitable form; or that there may be some form of irritation or inflammation other than you have detected; or the constitution and idiosyncrasy of the patient may be such as to render it injurious instead of beneficial.

I feel as though I could not conclude this paper on the use of alcohol without an additional word of caution as to its *abuse*. Of all men, the doctor especially should be free from encouraging by precept or example the habitual employment of alcohol. Its daily use tends to disease, to shortening of life, to lessening its enjoyment. It was a severe definition, but one, unfortunately, not farther from the whole truth than such definitions generally are, which was given by the late Rev. Dudley A. Tyng,—"The man to whom even one glass of liquor a day is a *necessity*, is a drunkard."

NOTES ON A CASE OF THROMBIC ABSCESS, ASSOCIATED WITH DIFFICULT ERUPTION OF DECIDUOUS TEETH.

BY J. E. GARRETSON, M.D.

AMONG the first of the days of the last month I was invited by a professional friend to see his child, an infant one year of age, laboring under the difficulties of a multiple tooth-eruption. Examination of the mouth discovered six bag-like cysts overlying the regions of six different teeth; neither mouth nor system was feverish, but the irritability at large was most marked. In lancing the different cysts, each ejected with considerable force its serous-like contents; yet, quite contrary to expectation, no amelioration in the irritability resulted from the operation.

Next there developed in the right gluteal region an abscess of a cold nature, which with great quickness involved the inter-muscular tissue, and found its way into the perineum, sloughing out in mass the cellular structures of the ischio-rectal fossa. After a week this extensive abscess yielded to the opposing forces of nature, and the parts filled up rapidly, affording promise of speedy cure. As, however, the process of granulation in this first abscess was completing itself, a

second developed in the deltoid region of the left shoulder; the inflammation here was of the subacute variety, and was treated with alternate applications of antiphlogistic and slightly stimulating medicaments. This inflammation, after a few days, involved the subclavicular region, and extended itself (yet not threateningly) into the axillary space. The matter formed was of course vented immediately on its presence being verified. This second abscess (while in process of cure) was succeeded by a third, developed in the apex of the lung of the same side; and the progress and maturation of this placed the life of the child in the greatest peril, for two days all hope being abandoned.

Recovering from this, still another abscess—in this instance presenting alone primarily the expression of a serous effusion—showed itself in the right parietal region beneath the temporal muscle. In this lesion, the rapidity of the accumulation, together with the entire absence of inflammatory phenomena, inviting examination, the exploring-needle was used, with the result of discovering the effusion to be blood, and not serum, as was inferred. On the sixth day from its commencement, so great was the effusion and so decided its direction towards the zygoma that it became necessary to make an incision. This allowed of a discharge, which consisted of about equal parts of blood and pus.

Happily, throughout the progress of the case the appetite of the child continued, and no difficulty was experienced in the free use of cream and brandy; this stimulant, and Churchill's syrup of the hypo-phosphates of lime and soda, being the only medicinal remedies which it was thought necessary to use. The abscesses terminated with the one in the scalp, and the recovery was so complete that the health of the child at this date seems quite as good as before the attack.

This case was evidently one of multiple thrombic abscess, and in no sense of the word septicæmia. The condition of the system of the little patient during the progress of the abscesses, and the immediate and happy recovery, exhibit, as it would seem, the purely mechanical expression of the different stages.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF R. J. LEVINS, M.D.

Reported by Dr. JOHN B. ROBERTS.

CASE OF MULTIPLE ENCHONDROMA OF THE FINGERS.

THIS boy, eleven years old, presents himself with a remarkable deformity of the left hand, caused by the presence of a large number of cartilaginous tumors connected with the phalanges. The history states that five years ago the affection was first observed on the back of the hand near the knuckles, since which time the tumors have been forming upon the fingers, and continually, though slowly, increasing in bulk.

There is also a large mass upon the humerus at the elbow, and another connected with the ulna, producing partial luxation of the joint, by which complete extension is prevented, but not flexion. The inferior extremity of the ulna, which is somewhat misshapen by excessive curvature along its shaft, is imperfectly developed, so that the bone is too short, and gives the wrist an unusual contour. The largest masses of enchondromatous materials are situated upon the first phalanges of the second, third, and fourth fingers, and also upon the second phalanges of the second and third fingers, while smaller tumors are seen connected with the remaining phalangeal bones. The motion in the

joints is restricted, and in some places there is partial luxation, although the greatest bulk of the tumors, in most places, seems to be upon the shafts of the phalanges. There is some deposit at the distal ends of the metacarpal bones, and, owing to abnormal relaxation, the fingers can be bent backwards until they stand at a right angle with the metacarpus. There is no pain in the tumors, which are benign, and only impair the function of the hand by their bulk, which prevents the free use of the fingers; the boy can grasp large objects quite firmly, but delicate manipulations are impossible.

These tumors, which at a distance resemble osseous nodules, have a peculiar elasticity, and are simply masses of cartilage developed in the cancellated structure of the bones. This enchondromatous material has the character of the cartilage found in foetal life, and may be deposited in various situations,—as in the testicle or in the parotid region, as well as in bone. The disease is quite common in bones, and is one of the most frequent causes of benign tumors seen upon the fingers. Occasionally, but very infrequently, the growths assume a malignant character, and then may be followed by the gravest consequences.

“The diagnosis of enchondroma is almost unmistakable, but errors have been made by supposing such tumors to be tensely-filled cysts, on account of their peculiar elasticity simulating an indistinct fluctuation. This error would be most liable to be made with enchondroma in or about the parotid gland. It should be borne in mind that the hardness of enchondroma, when not ossified, is never so great as that of normal cartilage, such as the costal, tracheal, and laryngeal cartilages.

“The microscopic appearance of the structure of enchondroma shows a remarkable want of uniformity of cell-form and arrangement, and this irregularity is greater than in any other form of benign tumors.

“Enchondroma of the hand seems to be almost invariably associated as to its origin with childhood, or is congenital; and experience shows that the increasing development of the tumors usually ceases at the age of maturity. It has been remarked that the thumb is generally exempt from such growths, even when all the other fingers are affected. Although enchondroma of bone in general varies much as to its exact origin, in the hand the tumors always originate within the bony structure.

“In the ordinary location of such tumors, as on the long bones and the bones of the pelvis, there are many recorded instances of their enormous development. In one case, in which the tumor was developed around the entire shaft of the femur, its circumference was three feet, and the patient was relieved of the increasing burden by a successful amputation at the hip-joint. A cartilaginous tumor, involving the upper part of the tibia of a child, attained a circumference of two feet during a period of but eighteen months; and John Hunter removed an enchondroma, developed from one side of the face, which weighed after extirpation nine pounds.”

The affection is not amenable to treatment by medication, and excision of the growths or amputation of the members affected would be altogether improper in this instance; therefore the boy must be content to carry this deformity with him throughout life.

BELLEVUE HOSPITAL MEDICAL COLLEGE.

SERVICE OF PROF. LEWIS A. SAYRE.

Phonographically reported by WILLIAM A. GEORGE, M.D.

POTT'S DISEASE—NEW METHOD OF TREATMENT: FIBROUS ANCHYLOSIS OF HIP: TALIPES—SECTION OF PERONEI MUSCLES: FIBROUS ANCHYLOSIS OF KNEE: INFLAMMATION OF KNEE—LOCALIZED TREATMENT BY ACTUAL CAUTERY: TWO CASES OF CARBUNCLE, ONE FOLLOWED BY ANCHYLOSIS OF FINGERS, THE OTHER, BY NECROSIS OF BONE: SUPPOSED FRACTURE OF NECK OF FEMUR SIMULATING HIP-DISEASE—CHLOROFORM.

THIS child, four years of age, was brought to my office six weeks since, from the country, with Pott's disease, or posterior angular curvature of the last two dorsal and first upper lumbar vertebræ, unable to stand, very much emaciated, and the right limb paralyzed,—probably from pressure upon the spinal cord. The child had suffered the usual symptoms of this disease for more than a year past, having been treated for worms, incontinence, and pain in the stomach, the disease of the spine never having been suspected until a few weeks ago, when the physician who had the child in charge sent him to my office.

The patient's parents were too poor to buy a Taylor's brace which I intended to put upon it, and the disease, in fact, had so far progressed as to require of the child the recumbent position for some time before even a Taylor's brace could be used to advantage. As I before said, they were too poor to buy any mechanical apparatus, and, as perfect quiet of the spinal column was requisite, I had the child held up by the arms (the weight of the body acting as an extending force), pinned his little flannel shirt around his thighs, stretching it over his body smoothly, and, commencing at the pelvis, applied rollers saturated with plaster of Paris to his entire trunk, the same as you would to the thigh in dressing a fracture.

The only fear I had in making this application was of constricting the chest so as to interfere with respiration; but, as the child cried lustily during the whole operation, this fear was removed. He appeared able to press the diaphragm down so as to give plenty of room for respiration, notwithstanding that the dressing was entirely around the thorax.

He was held in this position, suspended by the arms, for twenty or thirty minutes, until the plaster became set. Then the cuirass, as it might properly be called, was divided in the median line from the sternum to the pubis, when, of course, his respiration became perfectly easy. The lower portion around the pubis was then secured by a roller, making it a firm support, and the upper portion of the dressing was tied at various points by an elastic bandage, allowing the upper por-

tion to expand for respiration, and, as his parents say, he has been perfectly comfortable ever since, has grown quite fleshy, and is now able to walk about without resting his hands upon his knees.

This child was brought to me again an hour ago, and I have brought him to you to show the practical effect of the application of this plaster-of-Paris dressing, as it is the first time I have used it in this way. I have frequently employed the plaster extending two-thirds around the body, which I have termed "turtle-shelling," but never before carried it clear around, encircling the entire body. As you all know, the streets are nearly impassable from the small icebergs interspersed here and there, and therefore we have been jolted in the most severe manner, and yet the child has never complained at all, although the parents say that it was impossible to move him before without using the greatest care.

We will remove the cuirass, which is for the first time since I applied it six weeks ago. The angle of the curvature is very much less sharp than when the instrument was applied, and the child's general health has improved immensely. [The professor then showed the plaster cast to the class, the mother holding the child in her lap in the mean time. It was then readjusted, when the mother remarked that the child could now sit up, but when the dressing was off it could not sit up at all,—which, as the professor mentioned, was the best proof of the efficacy of the treatment.]

The advantage of this plan is that it is very simple, very economical, the material for its construction attainable anywhere, its ease of application, the readiness with which it can be readjusted as the growth of the child requires, and the accuracy of the fit, giving the child more comfort than any instrument which could be made, unless over a plaster model, which would be very expensive. The objection to the use of plaster is that it is not very clean; but this can be obviated by using starch, flour, and eggs, silicate of sodium, or any thing else that will assume the shape of the body and retain that form.

When the disease occurs in the cervical region there must be a support for the head. Taylor thinks he obtains this by a support under the chin, resting on the shoulders. This, however, will not answer the purpose, for, if the brace be sufficiently slack for a patient to eat, there certainly can be no extension.

Case II.—This little girl now before you, gentlemen, is the same one that was here two months ago, with an ankylosed hip, with the leg strongly adducted across the opposite limb, and the foot inverted, the deformity being that which results from nature's cure of hip-disease.

To rectify this distortion you will, perhaps, remember that I divided the adductor muscles of the thigh and advised an extension-splint with abducting screw, since which time I have not seen her, in the mean time she having been treated by my son.

Examining her, I find the result has been much better than I at the time of the operation anticipated. Here, when we hold the pelvis still, we obtain motion at the hip-joint, flexion, extension, abduction. This, gentlemen, is a case in which massage would be of great benefit. She has no pain, and by having the limb in a position to enable her to walk, her own exertions will greatly aid in perfecting the motion of the joint.

Case III.—This, gentlemen, is the case which was before us some three weeks since, suffering from double club-foot, equinus in the left, and equino-valgus in the right, the sequel of an attack of diphtheria when one year old, the deformity being of fifteen years' standing. You will remember at that time I cut those tissues upon which point pressure produced reflex contractions,

and by this test we found that in the left foot the plantar fascia, and in the right the tendo Achillis and peronei muscles, required division, it being the first time in my life where I had seen this contracted condition engrafted on a former paralyzed state of the muscles. After the operation he was dressed in my usual way, and went home. To-day he returned for the application of elastic force.

Upon an examination, we find the trivial wounds healed, the feet capable of being brought into a normal position and retained there, and the tendons which were severed firmly united. He as yet has had no electricity or friction to bring out the vitality of these muscles, but you notice he has perfect control of those divided, and you will recollect when I cut these tendons I restored the foot at once to its natural position, and did not wait, as some advise, until the tendons united before attempting restoration of the parts. I always replace the foot in its proper position immediately on section of the tissues.

But suppose, now, gentlemen, I let this lad go without any instrument to retain his feet in place: what would be the result? Why, in a very short time he would be as badly off as before the operation was performed. The proper treatment of talipes does not consist alone in restoring the foot to a normal position, but in retaining it in that position by mechanical means until sufficient vitality has been secured to the parts, by electricity, massage, etc., to hold it there. And the mechanical means which I here use is a shoe having appropriate joints, and to which are attached such artificial muscles (made of rubber) as the weakness of the parts require. He will also need an everting screw to correct the tendency to inversion of the left foot.

Case IV.—This boy, six years old, has suffered for five years from disease of the left knee-joint, and, although he has recovered from the disease itself, it has been with the usual distortion peculiar to these inflammations of the knee-joint, and with limited motion.

He measures as follows: Left limb, thigh, 8 inches; calf, 6½ inches; knee, 9 inches. Right limb, thigh, 10 inches; calf, 7½ inches; knee, 8 inches. Both the legs are of the same length, so far as I can measure, allowing for the flexion. The flexion in this case is nearly at right angles, and is due to the neglect of passive motion during the progress of the disease.

The treatment consists in the application of the same principle of which I have so frequently spoken to you,—namely, the restoration of vitality to the parts, and the restoration of the parts to their normal position. The adhesions here are not so firm as to require *brisure forcée*, and the prospect is good that by means of an extension-instrument with an appropriate joint he can be perfectly cured of his deformity.

Case V.—This, gentlemen, is the little girl who was here last week, and who gave us the following history, as we learn from the stenographer's notes: "N. M., aged 6, has been ill for two years, complaining of pains in the knee which were thought to be 'growing pains,' and which also were supposed to be due to a fall upon the knee. She suffers from pain principally at night; is on her feet all day. Has been gradually wasting in flesh. The family are all healthy with this exception, and the patient had good health previous to the fall. Examining her, there was found to be little if any effusion, a slight increase in temperature, but no redness. There was no pain upon extension, thus excluding the soft parts from the disease; but, upon pressing the ends of the femur and tibia together, at the same time adducting the leg, the pain was severe, showing at once that the inflammation was limited to the inner portion of the articulation, especially as compression with abduction was negative in its effect. By pressing, now,

with our finger, we find the seat of pain at the top of the tibia, where the coronary ligament holds the semilunar cartilage in place."

The child presents the same condition to-day, and the treatment, as I suggested last week, will be the actual cautery. There is no use of strapping, as there is no effusion to be absorbed. Why the actual cautery is best for these cases I do not know, unless it relieves inflammation by shrivelling up the blood-vessels. [The child was anaesthetized, and the operation performed.]

That, gentlemen, is the way to give chloroform: at least, that is the way I give it: a very few drops sprinkled on a handkerchief, and applied close to the face, without admixture with oxygen. I know this method of using chloroform for the production of anaesthesia is contrary to the teachings of all the books. I am fully aware that it is in direct antagonism to the opinion of many distinguished men; but chloroform given in this manner does the work, and, so far as my experience goes (and I administer chloroform six or eight times daily, in all classes of cases), it does the work speedily and safely.

What do you give chloroform for, except to produce anaesthesia? Oxygen is its antidote, and resists its effects. Then why do you give the antidote, which prevents you from obtaining the influence of the drug, when by giving the vapor of chloroform pure and unimpregnated with oxygen it produces its results at once, and with but the minimum quantity? Then, if by some mishap, some peculiar idiosyncrasy of your patient, respiration ceases, a few artificial respiratory movements are all that is required, and the five or ten drops instead of five or ten ounces which have been used are rapidly eliminated from the system, and the patient is rescued from impending death; but if there be a pound of the agent which has been gradually introduced into the patient's circulation, what hope have you—what hope *can* you have—that success will attend your efforts at restoration?

Chloroform is a deadly poison, as strychnia, arsenic, prussic acid, but who ever heard of their being given by the ounce or pound, in connection with their antidotes, in order to attain their effects? No; the doses of these drugs are carefully gauged, and the very same reason which prompts the physician to regulate the doses of strychnia, arsenic, and prussic acid should deter him from giving chloroform in such large and indefinite quantities.

Now, one point in applying the hot iron. You noticed I held it firmly, very firmly, to the knee. And why? Because an evolution of gas takes place, and unless securely held your instrument will slip from the point, and instead of having a linear eschar at the exact spot desired, as the result of your operation you will obtain a half-dozen bad burns, perhaps exactly where you did not desire them.

There is but little pain attendant upon the operation. From some cause, burning with an iron at white heat is the best local anaesthetic we have, and frequently when the operation has been performed once, and it becomes necessary to repeat it, the patient refuses an anaesthetic.

Cases VI. and VII.—Negress, 35 years old. Two months since, she had a carbuncle on the ulnar side of the palm of the hand, which was allowed to pursue pretty much its own course, and finally healed up, leaving her hand in the ankylosed condition which you here see (fingers clenched and rigid).

In this other case, a blacksmith, you observe a different result. In the case of the negress we have fibrinous ankylosis of the fingers, due to the adhesions of the theca to the tendons, while here we have extensive suppuration, sloughing of the dense palmar cuticle, and exposure of the bone; besides, this case is but of a week's standing. These inflammations beneath the

palmar fascia, known as "frog felons," are of frequent occurrence, are intensely painful, and sometimes lead to disastrous results. Suppuration taking place beneath this dense tissue, there is no place for the easy escape of pus, and consequently it burrows in every direction, producing infinite mischief.

The treatment consists in an early and free incision; and if the inflammation be beneath the periosteum, as it frequently is, it must be laid open as well, otherwise necrosis of the bone will follow.

Of course, the only thing left for us to do in the treatment of the first case is simply to administer an anaesthetic and break up the adhesions, and give the patient instructions to use and work her fingers as much as possible after she goes home.

But in the case of this blacksmith, I fear the ring-finger will have to be removed. When he came to me yesterday, I laid open the parts, but whether in time to save the finger I cannot as yet say. I will extend the incision I made yesterday, but if simple exfoliation of this denuded bone does not take place, the finger had better be removed early. [Both operations were then performed.]

Case VIII.—Here, gentlemen, is a woman, aged 35, with an enlargement upon the upper and outer portion of the left thigh that has a peculiar rounded shape. There are two sinuses here; one over the trochanter major, and the other opening half-way down the thigh, the latter presenting the characteristics, first pointed out by the late Dr. Stevens, of leading to dead bone. I have never yet seen a sinus having the appearance of the cloaca of the hen, that did not communicate with necrosed bone.

This woman states that she has been laid up for three years with this trouble, has been under treatment and has had extension applied, evidently by some one who thought she had hip-disease.

By holding the pelvis still, and pressing with great force against the acetabulum, I produce no pain, and can obtain slight motion without pain; but if we make the motion too extended she suffers, owing, I presume, to the extra-capsular inflammation, and by this means we exclude disease within the joint proper. By the use of a soft, flexible probe like this, as I supposed, here we find necrosis of the femur which does not involve the joint. By inserting the probe at the lower opening it passes upward seven inches, and grates on dead bone near the great trochanter; and by a tortuous course which this flexible probe readily follows, I find this upper sinus communicates with the same necrosed bone.

In the further examination of this case we discover she has the exact position which generally follows fracture of the neck of the femur,—shortening and eversion; but the patient declares that she never had fracture.

We will now put the end of the tape on the tuberosity of the ischium, and, carrying it around to the anterior superior spinous process of the ilium (Nélaton's test), we find the trochanter major above the line, showing that there has been fracture of the neck of the femur, dislocation or else disease of the acetabulum, allowing the head to ascend. But if it had been hip-disease, third stage, there would be inversion of the foot, and not eversion; besides, I have motion in this joint almost too free to admit of there having been hip-disease. It is barely possible that the disease might have progressed, and the limb assumed this peculiar position owing to artificial traction; but my diagnosis is that this is a case of fracture of the neck, which has united, throwing out an enormous amount of callus, imprisoning dead bone, and that this necrosed bone is the cause of the discharge which has been kept up for three years.

In the treatment of this case, I shall simply dilate this lower opening: to make an incision seven inches long in a woman who is run down like this one, is a very serious matter, and by dilating this lower opening with a sponge tent or piece of laminaria, and putting in a drain-tube, it is very probable that the small portion of dead bone will come out of itself, and by the use of a splint with an abducting and inverting screw we will try to rectify the deformity. Of course she is to have fresh air, good beef-steak, and plenty of exercise, which the use of the splint will enable her to take. By these means, I think, she will get entirely well, with an exceedingly useful limb, as the shortening can be overcome, in a manner, by an extra lift on the heel and sole of her left shoe.

This case, gentlemen, is very interesting, from its simulation of hip-disease, and for which it could readily be, and has been, mistaken.

TRANSLATIONS.

THE VASO-DILATIVE ACTION OF THE GLOSSO-PHARYNGEAL NERVE ON THE MUCOUS MEMBRANE AT THE BASE OF THE TONGUE.—M. Vulpian presented at a recent meeting of the Académie des Sciences a note on this subject, of which the following is an abstract. Curarized dogs in whom artificial respiration was maintained were used for experiment.

After having exposed the glosso-pharyngeal nerve below the base of the cranium, it was tied, and then cut above the ligature, so that its peripheral extremity could be excited by electricity.

No change in the appearance of that portion of the mucous membrane of the tongue supplied by this nerve, the posterior, from the epiglottis in a V-shaped direction to the calciform papilla, was observed, excepting slight and transitory congestion. An induced current passed through the peripheral portion of the nerve caused redness of the lingual mucous membrane on the same side in the locality mentioned. This red color was particularly intense in the neighborhood of the anterior half-arch, and extended to the tonsil. The inferior surface of the tongue became congested at the same time, but to a less degree. The vessels of the congested parts could be seen to be enlarged, and the temperature of the mucous membrane was somewhat increased, but it was not moist. The effect of faradization lasted some time, and could be renewed at pleasure. These results are the same as those obtained by cutting, on the same side of the same animal, the lingual nerve at its superior part, the hypoglossal and the pneumogastric close to the cranium, after having, in addition, excised the superior cervical ganglion. The same results are observed in an animal poisoned with sulphate of atropia. The mechanism of this vaso-dilating action of the glosso-pharyngeal is undoubtedly the same as that exercised by the fibres of the chorda tympani which accompany the lingual nerve to its extremities.

Further experiment showed that the vaso-dilative fibres contained in the glosso-pharyngeal are not present in the facial.

Finally, the vessels of the mucous membrane of the tongue are everywhere under the influence of vaso-dilative fibres. In the anterior part of the tongue it is the lingual which supplies this action by means of anastomotic fibres received from the chorda tympani; in the posterior part of this organ it is the glosso-pharyngeal by which, as has been shown, this office is performed.

JABORANDI.—M. Gubler presented to the Société de Thérapeutique recently two specimens of jaborandi,

one of which had been sent to him by M. Coutinho, the other taken from a lot consigned to a drug house in Paris.

These two specimens resembled each other closely, and seemed to belong to the same species (*Pylocarpus pinnatus*); their action was identical. A patient to whom M. Gubler had administered four grammes of this new jaborandi perspired very freely, and gave about a litre of saliva. The branches seemed to have an action similar to that of the leaves, and nearly as intense.

The administration of jaborandi is appropriate, M. Gubler thinks, under all circumstances, and in any disease. It occasionally produces vomiting, particularly when it is not administered fasting. Other effects are, production of violent thirst, and, occasionally, considerable swelling of the submaxillary glands. Jaborandi is indicated, accorded to M. Gubler, in anasarca and effusions of all kinds, subacute articular rheumatism, bronchitis with asthma (M. Gubler has had remarkable success in preventing attacks of the latter affection), and influenza. It may also be recommended as a substitute for calomel, especially in ophthalmia, when it is desired to induce salivation. X.

A CASE OF CEREBRAL RHEUMATISM TREATED BY COLD BATHS.—M. Blachez communicated the following observation to the Société des Hôpitaux (*Bull. Gén. de Thérap.*, February 28). A woman thirty years of age was attacked by the first symptoms of rheumatism on the 14th of January. On the 16th the rheumatism was fully developed. On the 18th the articular pains disappeared, the fever becoming more intense. On the 19th delirium supervened, the pulse rising to 118. On the 20th, condition worse; violent delirium, pulse 156, temperature 107.2°; the case seemed desperate. After consultation, the first bath, reduced by ice to 78°, was administered. The patient, after remaining immersed for an hour and a half, showed a pulse of 96 and a temperature of 101.1°.

From the 12th to the 24th twelve baths were given, the temperature of these baths ranging from 73.4° to 77°. Under the influence of these a gradual amelioration of the patient's condition was brought about. On the 25th the temperature was 99.3°, and the pulse 96; consciousness returned by degrees. By the 27th the patient was convalescent, and on the 5th of February she went out for the first time. X.

THE LESIONS PRODUCED BY ERYSIPELAS.—Dr. Renault (*Archives Gén. de Méd.*, March, 1875) formulates his ideas upon this subject as follows:

1. The lesions produced in the skin by erysipelas are those of a simple inflammation, a *dermatitis*; the latter characterized by two anatomical periods: (a) infiltration of white blood-globules into the derma, corresponding to inflammatory oedema; (b) proliferation of fixed cellules, less transitory, and which appear to play an important part in the induration consecutive to erysipelas.

2. The infiltration of the white globules into the derm takes place by exudation. The white globules are brought by the lymphatics of the blood-vessels.

3. They are taken up for the greater part by the lymphatics, and when the transportation is very active the latter become inflamed consecutively.

An endolymphangitis, a lymphangitis, or a perilymphangitis may be brought about. The passage of the white blood-globules in the lymphatics occurs in the lymphatic spaces of the skin channelled in the middle of the fasciculæ of connective tissue.

4. In intense erysipelas the adipose tissue becomes inflamed, and returns to the embryonic condition, taking a prominent part in the primitive and consecutive erysipelatous induration. X.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, APRIL 10, 1875.

EDITORIAL.

PROFESSIONAL ADVERTISEMENT.

THE subject of professional advertisement, upon which we have had occasion to speak at various times, seems to be attracting very wide attention at present. We think such attention is extremely necessary in certain quarters, and in no place is it required more urgently than in the neighboring city of New York. If our medical friends there continue as they have done to use increasingly the *Tribune* as their means of communication with the profession, we will have to withdraw our subscription from our old favorite, the *Medical Record*, in favor of its more pretentious rival. We are not surprised, therefore, that the *Record* is discussing the matter with more boldness than formerly. Indeed, one of its recent editorials might have been mistaken for the product of the pen of "an Ishmaelite." The New York societies are certainly to blame in this matter; some of their most prominent members seem to have abundantly and openly transgressed the Code of Ethics, and the *Record* is undoubtedly correct when it says, "The medical man himself is alone responsible for allowing himself to be used as a means of sensationalism in any shape." The following challenge to the societies contains so much that is true and suggestive that we offer no apology for extracting it from the columns of the *Record*:

"Believing it to be our duty to be outspoken in this matter, we, even in this day, when newspaper advertising is timidly winked at by our County Society, dare question the right of any medical man to laud himself at the ex-

pense of his more deserving but less modest confrères. We care not who this man may be, whether a professor, a president of a society, or a leading practitioner, he is always amenable to discipline, and should, when found guilty, always be punished. If punishment cannot be inflicted without the fear of offending, then let us abolish our code of ethics, let the county societies alter their by-laws, and cease their presumptuous censorship of the profession. The Committee on Ethics may take up the case of some obscure individual, who, without influence and without friends, may be forced, in the face of starvation, to get business by unorthodox measures, and may annihilate him by expulsion. But how is it with some prominent men who presume to transgress the code with impunity? We have yet to hear of one who has ever been brought to account."

We fear the only answer which will be given this will be some senseless personal abuse of the editor who penned it; but nothing would better clear the professional atmosphere throughout the country than a thunderstorm in New York. The present tendency to neglect of ethics largely had its origin in that city, and the expulsion of one or two prominent men from the societies would render professional advertisement unfashionable for some time to come.

WE have been asked to call attention to the following circular:

"Some of the descendants of William and Samuel Tuke (the former of whom proposed the establishment of the York Retreat in 1792, and the latter wrote the 'Description' of the humane system of treatment commenced there) having placed at the disposal of the Medico-Psychological Association the sum of one hundred guineas, the Association offers a prize of this amount for

"The best series of original Cases and Commentary, illustrative of the Somatic *Ætiology* of various Forms of Insanity, accompanied, when possible, in fatal cases, by reports of post-mortem examinations and microscopical preparations,—their bearing on the symptoms being pointed out.

"Cases not seen by the writer may be cited, but must be distinguished from those actually witnessed by himself.

"The W. and S. Tuke Prize is open to all without restriction as to country, profession, etc., but the right is reserved to withhold it should there be no essay of sufficient merit. Essays, to be written in English, and not in the author's handwriting, to be sent with a sealed envelope, bearing the motto of the essay, and containing the name of the writer, to the undersigned, not later than June 30, 1876. The microscopical preparations, but not the essay, to belong to the Association.

"W. RHYS WILLIAMS, M.D.,

"Hon. Sec.

"BETHLEM ROYAL HOSPITAL, LONDON."

CORRESPONDENCE.

SOUTH OIL CITY, PA., March 6, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

ON the 16th of November last I was called to see a boy aged 4 years, who was suffering from strangulated inguinal hernia. After making the usual attempt to reduce by taxis, I resorted to the use of chloroform. Still finding the reduction difficult, I had the lad suspended by the feet, the head hanging down, while I continued my efforts at reduction. After hanging three or four minutes, the chloroform-narcosis was so far overcome that I thought it necessary to administer more of the anæsthetic. For this purpose he was placed on his back, when, almost instantly, he became insensible, and, although I continued my manipulations of the hernia, continued so till I again ordered him to be suspended as before, when in a very few minutes—I should say three or four—he again aroused, and cried out. As the hernia was yielding, I retained him in position till it was returned, when I placed him on his back, and he immediately became unconscious, and went into a profound sleep, which lasted some fifteen minutes. I report this case as confirmatory of the theory of Nélaton, that chloroform-narcosis causes an anæmic condition of the brain and spinal cord.

Yours truly,

F. F. DAVIS.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, FEBRUARY 11, 1875.

THE PRESIDENT, DR. WILLIAM PEPPER, in the chair.

Aneurism of the aorta, with supposed rupture of the heart.

DR. JOHN GUITERAS presented the specimen, and read the following history:

"As the nature of the case was not suspected during life, the history I have been able to obtain from the attending surgeon, and the notes on the autopsy, are necessarily very imperfect.

"H. M., æt. 40, admitted into the medical wards of Blockley Hospital on the 4th of November, 1874. No careful examination was made of his condition; and, as he had a sore on the face, he was transferred the next day to the surgical ward. Here he was treated for syphilitic necrosis of the nasal bones. Besides this, he rather frequently called for relief in attacks of bronchitis, which soon yielded to treatment, and never made necessary a physical examination. Nevertheless, the man was weak, and indisposed to move. He was short of breath, and kept a good deal to his bed. To get a good night's sleep he required anodynes, and preferred to lie with the shoulders elevated.

"On the 13th of January he felt better than usual, and did not take his evening dose of morphia. At 11 o'clock the night-nurse heard him blowing as if to spit up something. A few minutes after, the doctor found him tossing about in the bed, and gasping for breath. He was able to utter short, interrupted sentences. The skin was purple, cold, and clammy. No pulse could

be felt, except, perhaps, at the carotids. Though the movements of the patient prevented all attempts at auscultation, the condition was diagnosed as one of heart-failure, and was treated accordingly. At 1 o'clock A.M. he died in a condition of syncope. The urine removed before death was not albuminous.

"Autopsy.—The cartilage-knife was made use of to cut the costal cartilages over the heart. In removing the sternum, a piece of the pericardium, about two inches in diameter, was shaved off; a considerable amount of blood ran out, and a clot was seen bulging through the opening. This clot filled up the pericardial sac, was half an inch thick, measured six by five inches, and weighed eight and a quarter ounces. It was recent, as shown by its dark color and jelly-like consistency. On removing it, a small projection from it appeared to be entangled in the cardiac walls. On grasping the vessels at the root of the neck, blood was seen to well out of a small slit in the anterior wall of the left ventricle. When the thoracic viscera were removed, it was found that the arch of the aorta was dilated into a large aneurism, the upper wall of which was left in the body.

"I saw the specimen a few days after its removal, and was led to doubt the existence of cardiac rupture. Examining it carefully, I find that the heart is enlarged. The deposit of fat around it is abundant, especially about the right ventricle. Less than one inch from its origin, a large dilatation of the aorta begins, and extends somewhat beyond the origin of the left subclavian. It might hold a large orange. Its outer surface is very ragged; the inner surface is covered with irregular layers of fibrin, which have broken down in some places, leaving the sac-walls very thin. On its anterior wall, in the ascending portion of the arch, there is a place where the thrombus is deeply excavated, and at the bottom of this excavation the adventitia seems to have been perforated. On filling this portion with water, the liquid leaks, drop by drop, through the opening.

"The left ventricle is moderately dilated and hypertrophied, its walls measuring half an inch. The right ventricle is not dilated, and its walls measure from one-sixth to one-eighth of an inch. Just to the left of the inter-ventricular septum, and one and a half inches from the apex, the slit is found. It is directed downwards and outwards, and measures less than half an inch. Its edges are perfectly smooth, very much resembling an incision. The upper end runs straight into the cavity, whilst the lower end runs slanting to meet the upper one; thus leaving a very small opening on the endocardial surface, so small that it was only detected by pushing a director from the outside.

"The valves are slightly thickened, but the endocardium in the cavities and at the seat of puncture is perfectly healthy. There is no lesion of the cardiac walls about the opening. The muscular fibres present the usual slight fatty degeneration common to all cases of hypertrophy with dilatation.

"In regard to the slight attachment of a portion of the clot to the viscus, it must be remembered that it did not lead to the discovery of the opening, but it was brought to mind after the slit had been found.

"The following reasons seem to disprove the existence of rupture of the heart:

"1. The presence of an aneurism of the arch of the aorta, a lesion which is so apt to terminate by rupture into the pericardium. The walls of the sac are very poorly organized, and at one spot an opening seems to have occurred during life.

"2. The pericardium, endocardium, and the muscle itself present no acute or chronic lesion that could have caused a rupture. The deposit of fat around the heart is not more than what I have seen in a good many cases.

"3. The features of the slit. It is a perfectly clean cut. The upper end leads perpendicularly down into the cavity of the ventricle, whilst the lower end slopes gradually almost to meet the upper one; thus representing the shape of the blade of a knife. Experimentally, I used the knife in cutting the costal cartilages of another subject, without being careful to avoid the heart, and I produced a slit similar in every respect to the one in our specimen.

"4. I also think that I found the trace of the knife in the clot; but this had been handled a good deal.

"The perforation was rendered particularly easy in this case by the clot of blood distending the pericardium, and by the layer of fat covering the anterior surface of the viscus; both circumstances tending to diminish the resiliency of the structures to the knife."

Dr. JAMES TYSON said he had seen the specimen immediately after its removal from the body of the patient. At that time a probe had been introduced through the opening of supposed rupture, but he was at once impressed with the resemblance of the orifice to that produced by a knife, such as often occurs when opening the chest rapidly. He was informed, on remarking upon this resemblance, that the orifice, when discovered, was covered by a huge clot of blood which appeared to render such an origin impossible. Dr. T. had no doubt that the orifice was produced by the knife in the post-mortem examination, and that the clot was probably due to a rupture of the aneurismal sac.

Obscure growths in the liver.

Dr. A. C. W. BEECHER presented, for Dr. J. C. NORRIS, the specimen, derived from C. L. J., aged 60 years, American, strictly temperate; had had no serious ailment prior to the sickness from which he died; never had venereal disease; no intermittent fever; no dysentery; no hæmatemesis; no dropsy. He was a confectioner until eight years ago, since when he had not been engaged in any business. His family for several generations was healthy; no history of cancer, consumption, or syphilis. The last sickness was of sixteen weeks' duration; he was deeply jaundiced after the first week. He was costive during the first six weeks, after which his bowels were moved daily without medicine, the stools being clay-colored from the first, and continued so until death.

There was no pain at any time in any of the abdominal organs, and no enlargement. Urine passed in normal quantity and deeply colored. He expectorated large quantities of frothy matter, occasionally colored with blood. He suffered from a great irritation of the skin, compelling him to scratch all night unless under the influence of anodynes.

The above history was given to Dr. Beecher by Dr. J. C. Norris, at whose request Dr. B. made the post-mortem examination, assisted by Dr. Isaac E. Roberts.

Post-mortem examination.—Skin deeply jaundiced, body somewhat emaciated, abdomen rather scaphoid.

The abdominal viscera were all deeply tinged with bilious coloring-matter; otherwise healthy, except the liver, which, though normal in size, had a hard mass of tissue at its transverse fissure, and surrounding the vessels entering there. There were a few hard nodules in the longitudinal fissure, and these were very small. The vessels entering the liver were markedly encroached upon in their calibre, the portal vein and hepatic artery being reduced to about one-eighth of an inch in diameter. The gall-bladder was not distended, and upon pressure there exuded a transparent straw-colored or yellow fluid of syrupy consistence. Upon plunging a scalpel into the substance of the liver, a fluid similar in character to that from the gall-bladder poured out: it was not so thick, however. The quantity amounted to several ounces. This fluid seemed to

come from the dilated hepatic ducts, which were very much enlarged; in the hepatic duct, just before it entered the cystic duct, there was a dilatation equal in size to a shell-bark. Though there was apparently no obstruction of the common bile-duct or of the cystic duct, yet the fluid in the liver did not exude under slight pressure.

The heart was small, but healthy; the lungs healthy, but some old pleuritic adhesions on the right side. No abnormal effusions in any of the cavities either of chest or abdomen. Kidneys healthy, but stained with bile.

Dr. S. W. GROSS asked whether the growths had developed from the secreting tissue of the liver or in the connective tissue about the transverse fissure.

Dr. R. M. BERTOLET, to whom the specimen had been referred for microscopical examination, said he had not had time to make a satisfactory examination. The sections he had removed contained nothing beyond connective tissue and fat-globules, further division of the growths being deferred until it had been exhibited. The tumor, when he first saw it, was about as large as a shell-bark, had surrounded the portal vein, and produced evident constriction. The matters contained in the gall-bladder and biliary ducts were bilious, and gave the usual reaction of the bile-pigments. If it should be scirrhus, it is certainly a very unusual site for it. There are, on the other hand, many clinical facts against it. In the first place, primary cancer of the liver is exceedingly rare; three-fourths of all cancers of the liver are secondary, and of these two-thirds are metastatic to primary growths in the visceral area of the portal circulation. Further, it has some suspicious appearances which suggest a gummy tumor, which, although usually occurring in multiple form, is sometimes isolated.

Dr. GROSS said his reason for asking the question lay in the fact that all the specimens of carcinoma of the liver he had seen had been developed in the substance of the liver, and not in the connective tissue, while it is well known that it is claimed that cancer is never developed in connective tissue, but only in glandular structures.

The PRESIDENT said that the specimen was one of great clinical rarity, whatever the nature of the growth might be. In carcinoma of the liver, masses of varying size are frequently seen developed from the glands or connective tissue in the transverse fissure of the liver, without actually involving the hepatic structure. The walls of the gall-ducts or bladder, or less frequently of the blood-vessels, may either become involved in the disease, or may be compressed so as more or less to obstruct the lumen. Nearly always in such cases there has been disease of other portions of the liver-structure associated; and he could not remember more than a very few instances where carcinomatous growths had appeared limited exclusively to the tissues in the transverse fissure of the liver. If this specimen be of malignant nature, therefore, it certainly should be regarded as of unusual interest.

Dr. BERTOLET said the latter question was answered by the fact that secondary cancers of the liver often could be clearly traced to cancerous thrombi in the vessels of the organ, the infecting mass being developed in and spreading from these thrombi. Virchow has even seen a thrombus of the portal vein undergo complete carcinomatous degeneration when there had been as yet no extension to the surrounding tissues. Naunyn goes so far as to say that all secondary cancers of the liver originate as cancerous degenerations of the thrombi,—that the majority of carcinomas of the liver start out from branches of the portal vein; but, as this growth lies outside and not within the lumen of the vessel, such a thrombic source is excluded.

Dr. B. stated that he had recently had the opportunity of studying several fine specimens of secondary hepatic cancer, and had noted that a peripheral or portal invasion of the acini seemed to be the rule, and that all attempts to inject the portal vein had signally failed.

The specimen was referred to the Committee on Morbid Growths, which reported as follows:

"The hepatic growth presented by Dr. Beecher consists of a dense whitish cicatricial tissue, in which are imbedded irregularly-shaped, yellowish, cheesy masses. The great preponderance of the gray fibrous tissue gives the growth a dense, scirrhous-like consistence. Bands of connective tissue permeate the growth in every direction, and, extending along the portal vein for a considerable distance beyond the point of constriction, render its walls thick and inelastic.

"Microscopically, the large nodule attached to the portal vein is made up of the fibrous tissue already mentioned, granular hyperplastic cells, and oil-globules. The central portions of the growth are in a more advanced stage of fatty and cheesy metamorphosis.

"There can be little doubt that we have here to deal with a mass of sclerotic tissue, the condensation and retraction of which have led to the partial stenosis of one of the branches of the portal vein and the occlusion of the adjacent biliary ducts; so that the latter can be readily traced to the surface of the organ, where they at times are dilated to the size of a crow's quill.

"No traces of a lymph or glandular structure could be discovered in any part of the growth. Whether the hyperplastic mass was irregularly called forth by syphilis or some other irritant the clinical history of the case perhaps may disclose, but, until the contrary is proved, your committee are inclined to regard it as a *gumma*."

BIOLOGICAL AND MICROSCOPICAL SECTION OF THE ACADEMY OF NATURAL SCIENCES.

FEBRUARY 1, 1875.

DIRECTOR W. S. W. RUSCHENBERGER, M.D., in the chair.

DR. J. CHESTON MORRIS, Chairman of the Committee appointed to examine optically the one-twenty-fifth and one-fiftieth objectives displayed at the late Exhibition of the Section, made a report, which was referred to a committee, and of which the following is an abstract:

The lenses submitted for examination were a one-sixth, one-tenth, and one-fiftieth made by Tolles, all immersion, a one-twenty-fifth immersion by Wales, and a one-fiftieth, dry, made by Powell and Lealand. The points which we considered it requisite for us to examine were, 1st, flatness and clearness of field; 2d, definition; 3d, penetration; 4th, resolution; 5th, angle of aperture; 6th, achromatism; 7th, amplification; 8th, working focus. Penetration or deeping is the property by which a lens shows us with tolerable distinctness objects or structures lying just within or beyond the best focal point or plane, and is of the greatest importance in tissue-investigations. [As a method for testing penetration (hitherto a desideratum), Dr. Morris proposes to examine a cover ground so as to be one one-hundredth of an inch thinner on one edge than its opposite, and to measure with an eye-piece micrometer the breadth of the band of ground glass distinctly visible (flatness of field being presupposed).] Again, resolving power is the property of showing certain lines, markings, or shadows on diatoms, etc., and may or may not co-exist with best defining power: it depends in great measure upon angle of aperture, and is to a great extent an antagonistic property to penetration. The dependence of resolving power upon angle of aperture is very

well shown by placing a *Pleurosigma angulatum*, for instance, under a one-fourth or one-tenth, with such an eye-piece as will amplify sufficiently, and putting the compound body horizontally in front of a direct light. In this position no lines will be seen, but by rotating the compound body on its axis an oblique light is obtained, which at different angles, according to the power of the objective, will bring out transverse or oblique lines, and finally dots appearing as hexagons. The following results were thus obtained:

POWER EMPLOYED.	TRANSVERSE LINES.	OBLIQUE LINES.	HEXAGONS.	TOTAL OBSCURATION.	ANGLE OF APERTURE.
Spencer's one-half inch, C eye-piece (lines beginning to show at 25°).....	25°			30°	60°
" one-fourth inch, C eye-piece.....	20°	25°	50°	60°	120°
" one-eighth ".....		20°	40°	65°	130°
Tolles's one-tenth immersion (lines broken into dots).....		80°	20°	85°	170°
Wales's one-twenty-fifth, immersion.....			0°	70°	140°
Powell & Lealand's one-fiftieth, dry.....		15°	0°	65°	126°
Tolles's one-fiftieth, immersion.....			0°	70°	140°

We found that the one-fiftieth of Tolles gave good results as to flatness and clearness of field, penetration, resolution, amplification, and working focus or distance. Its definition is only fair, as also its working angle of aperture, while as to achromatism there is much improvement to be desired, and in working focus and general usefulness much might be gained by setting the front lens less deeply and reducing the brass work of the face. We were, however, agreeably surprised by the facility with which it can be handled.

The one-fiftieth of Powell and Lealand was not equal to the above in clearness of field nor in definition nor in working focus. Its penetration was equal, as also was its amplification, but its angle of aperture was 14° less.

The one-twenty-fifth of Wales is a very superior lens, giving good definition, resolution, and penetration, whilst its other qualities are very fair.

The one-tenth of Tolles, although constructed mainly for use with oblique light, showed itself a good lens, with direct central rays, as to flatness and clearness of field, definition, amplification, and resolution; its angle of aperture is wonderful, while its achromatism and even its penetration are very fair, and its working focus sufficient.

From the observations noted above we deduce one very important fact, viz.: That the different appearances of lines, dots, hexagons, etc., on *Pleurosigma angulatum* are not only the varied results of angle of aperture, of amplification, and of illumination, but that they may be obtained with less and less obliquity of light as we increase the power of the objective; thus making it evident that high powers with direct central light show us clearly things which we rather guessed at than saw (owing to the increased chance of spherical and chromatic aberration and distortion from the employment of oblique light) with lower ones.

We would conclude, therefore, by recommending these high-power lenses to those engaged in microscopic research, not as capable of doing all work,—a one-inch is as indispensable to a histologist as a one-fourth,—but as likely to be proportionately useful in unravelling the mysteries of organic life.

DR. J. GIBBONS HUNT desired it to be distinctly understood that he had nothing to do with the preparation of the report, and did not wish to be held responsible as a member of the committee for the views advanced in it. He considered that it embodied the obsolete views of Carpenter and Beale in regard to penetration, which term should be dropped from the vocabulary of microscopists. He believed that penetration and resolution

can be and have been combined in the best objectives.

Dr. J. CHESTON MORRIS stated that the report was based upon a careful and conscientious examination of the objectives by the committee, and was in accordance with the well-known laws of reflection and refraction of light. He had submitted the report to Prof. George F. Barker (of the University of Pennsylvania), who had approved it so far as the optical questions were concerned, except, perhaps, on the subject of penetration, which he attributed to imperfect spherical correction. He could have wished that Dr. Hunt had expressed his dissent from the document as freely in private, when it was shown to him, as he had just done. All he did at that time was to suggest some slight alterations and additions, which being made, Dr. Morris was led to expect his adhesion to the report. As to the question of penetration being a useless one, he considered the presence of this quality in the lenses of Tolles of great moment. High angle of aperture and penetration have not been combined in the objectives of the German, English, and French makers to the same degree.

Dr. HUNT said that what one man calls penetration another does not, terms often being used without an exact knowledge of the meaning intended to be conveyed by them. He preferred a lens that will give one absolute focus rather than three indistinct ones. The conditions of testing are frequently fallacious, and imperfect illumination is one of the most prolific sources of error. With low objectives, as, for example, a one-fifth, used with the amplifier, very satisfactory and reliable results can be obtained.

In conclusion, Dr. HUNT proposed that at some time during the next year any resident member or members of the Section should prepare one dozen microscopical preparations, extemporaneous or otherwise, representing that many different departments of microscopical work, and exhibit the same at a meeting or meetings of the Section, under his own apparatus and in his own way, the object being to test men in regard to their technological skill, he offering to do the same. Those competent may compare and judge the results.

On motion of Dr. MORRIS, it was resolved that the Curator be authorized to purchase for the Section a Nobert's test-plate.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

CONVERSATIONAL meeting, Wednesday, January 27, 1875, at the Hall of the College of Physicians.

Dr. WILLIAM GOODELL, PRESIDENT, in the chair.

Dr. J. C. MORRIS read a paper on the "Use of Alcohol in the Treatment of Disease."

Dr. G. HAMILTON remarked that the numbers adduced by the lecturer were too small to admit any positive conclusions in regard to the comparative success of the moderate or immoderate use of stimulus in the treatment of typhoid fever. Other causes might operate. Long ago, in the hospitals of Paris, the disease had varied in its fatality during a series of years from one death in three, to one in twenty cases, under the same treatment and with similar surroundings.

The late Dr. William Gebhard, eight or ten years before his death, had said to him that typhoid fever had become so modified that he no longer regarded it as a very fatal disease.

Dr. ESHLEMAN said that in the experiments on Alexis St. Martin alcohol arrested digestion in the stomach. He does not hesitate to use it in typhoid fever, although he thought it was less used now than during the war.

The PRESIDENT stated that in the administration of

stimulants he was governed pretty much by one rule. When there is a craving of the system for alcohol, a few minutes after the patient has swallowed it his breath gives no indication of its presence. But when it is not needed, or when contra-indicated, his breath becomes loaded with its fumes. Apart from other positive clinical deductions, this peculiar tolerance of alcohol in certain stages of disease is in itself a strong argument for its value as a therapeutic agent.

Dr. ALLIS asked the lecturer the best mode of administering stimulants when the patient is almost bloodless, or suffering from shock.

Dr. MORRIS said he had assisted in some experiments upon St. Martin. Dr. Eshleman's statement was correct, but he thought quantity and habit had something to do in his case. Dr. M. said the object in cases of shock, such as referred to by Dr. Allis, was to arouse the powers. The pulse is small, thready, and life is at a low ebb. Put mustard on the stomach and brandy in it, the impression is immediately felt, and reaction sets in.

Dr. ATLEE said he had no experience in the use of alcohol. He had always dreaded it, and, in typhoid fever, gets along without it.

Dr. HAMILTON said in reference to the condition alluded to by Dr. Allis, characterized by repeated vomiting, rapid and feeble pulse, that the same thing was often seen in obstetrical practice, when excessive hemorrhage had completely exhausted the patient, and was probably dependent upon the exsanguineous condition of the brain and spinal marrow, and, as a sequence, deranged correlation of the entire nervous system.

Dr. LEE asked the experience of the lecturer of the use of alcohol in disease.

Dr. MORRIS said he had not seen any specific action. It is a tonic to the stomach, and may thus be used gradually with benefit, but he has seen tubercle develop during alcoholism. He believes in the contagiousness of tubercle. Some individuals are more susceptible than others, from constitutional predisposition.

Dr. STETLER asked Dr. Morris how he advised stimulants to be administered in such persons as our old friend Timothy, who are obliged to take them for their "stomachs' sake." In these cases Dr. S. thought they ought to be given after meals, and greatly diluted. If given too concentrated, they would rather retard than promote digestion. St. Martin's digestion was, he believed, good, and if whisky retarded it, as remarked by Dr. E., he probably took it in a too concentrated form. Dr. S. referred to the very successful treatment of typhoid fever at the Pennsylvania Hospital about twenty years ago (while he was a student there), when stimulants were given *pro re nata*.

The late Dr. Gebhard stated that he had treated seventy-five cases consecutively (some in private practice) without having lost more than one, and that one was a woman who came in with a tubercular complication, of which she died, and not of typhoid fever.

Dr. MORRIS said he was accustomed to give wine whey on the eighth or ninth day, so as to bring the pulse down to ninety, and keep the pulse round and full; afterwards milk-punch (1 to 5 of milk) once in four hours or oftener, so as to produce this effect. In enfeebled digestion he gives ale, sherry, hock, etc., at meals. In a concentrated form alcohol coagulates albumen, retards digestion, and produces chronic gastritis.

DEATH FROM THE USE OF PERCHLORIDE OF IRON.—A foreign cotemporary records a fatal instance of the use of a uterine injection of perchloride of iron. Peritonitis supervened soon after administration, and death occurred in thirty hours.—*Lancet*.

GLEANINGS FROM OUR EXCHANGES.

VALUE OF QUININE IN SCIATIC NEURALGIA.—Dr. D. I. Mackenzie (*Lancet*, March 6) had under his care a woman in whom sciatic neuralgia became developed, subsequent to injury received in a fall, by which the left thigh beneath the gluteal fold had been severely bruised. Three weeks after the accident the patient was seen by Dr. M., who ordered opium externally and internally, with hot turpentine fomentations. After two days a mixture containing ten grains each of iodide and bromide of potassium was ordered, and this treatment was continued for two or three days with some relief. At the end of that time it was observed that the disease had assumed a decidedly intermittent character, coming on in excruciating paroxysms at night. The bromide and iodide were then suspended, and quinine was given, thirty grains in divided doses on each of the first two days, the effects being carefully watched. On the third day the amount was diminished to fifteen grains. The large doses caused great deafness and noise in the ears, but the improvement was well marked. During the next few days quinine was administered only when the neuralgic symptoms were urgent; and on the 5th, for the first time, the patient got out of bed for a little. On the 7th, as the paroxysmal pain had given place to a constant aching, the iodide and bromide were resumed, but the quinine was again found to be necessary. From that date until the 19th, quinine was given nearly every night in ten-grain doses, and blisters, which were found very useful, were occasionally applied over the painful parts. During that time the symptoms were such as to leave no doubt of the efficacy of quinine. The pain began every morning about one o'clock; but if the patient was asleep it was not sufficient to awaken her until between two and three. If taken at ten P.M., the quinine did not entirely prevent the paroxysm. If taken at one A.M., it prevented it entirely. If the dose was not taken until three, the patient suffered for about half an hour after taking it, and then fell asleep. In consequence of the experience thus gained, the ten-grain dose of quinine was latterly left every night at the bedside for her to take when she felt the pain come on.

The improvement continued up to date of report, with every prospect of entire recovery.

PHOSPHIDE OF ZINC.—At a recent meeting of the Obstetrical Society (*Lancet*, February 27) Mr. J. Ashburton Thompson communicated a short paper exemplifying the advantage of employing phosphide of zinc in the treatment of chlorosis and anæmia. It succeeded in relieving the symptoms where iron had failed, and that rapidly. Phosphorus was of great value in the treatment of patients recovering from uterine hemorrhage, and in all cases of anæmia, and seemed to exercise a specific influence upon the neuralgia so often met with in these cases, encouraging the general nutrition of the body. Free phosphorus is not the treacherous poison it has hitherto been considered to be. It is a fatal and potent poison, it is true, but its therapeutic effects may be obtained with precision and perfect safety. If proper formula be employed, no apprehension of unexpected or uncontrollable poisonous effects of a therapeutic dose need hinder its general employment.

Dr. Routh said it might be known to some members of the Society that he had made several inquiries on the employment of phosphorus. In some cases it produced marvels, especially in cases, like those detailed by Mr. Thompson, due to deficiency of phosphorus in the system. But it occasionally acted injuriously, by producing headache and giddiness; and in a few cases (of idiosyncrasy perhaps) it acted as a deadly poison,

even in the first dose, sometimes immediately producing vomiting and syncope. The safest preparation was the phosphide of zinc; but it was a medicine always to be closely watched when given.

Dr. Tilt inquired what preparation of phosphorus Mr. Thompson recommended.

Mr. Thompson, in reply, said Dr. Routh had revived the old objection, not because it was a poison, but because we cannot calculate the results. These arose from decomposed phosphorus.

Dr. Playfair inquired whether the zinc phosphide was not insoluble in pill.

Mr. Thompson replied that some acid tonic given simultaneously would serve to assist in the decomposition.

SALICYLIC ACID.—The *Boston Medical and Surgical Journal*, March 11, contains an abstract of a letter received by Prof. Horsford from Kolbe, of Leipsic, in which the latter gives various details of interest relative to the use of this product. In the lying-in hospital of Leipsic it seems to have superseded carbolic acid as a disinfectant for the hands, vaginal douching, application to ulcers puerperalia, etc. It is used in solution in water of one part in three hundred to one part in nine hundred, or as a powder mixed with starch in proportion of one part in five. Kolbe recommends the trial of this remedy internally in the various zymotic diseases, in pyæmia, bites of dogs, etc. In order to prove its innocuousness he administered to himself and a number of students various doses of the acid, up to twenty-three grains a day. The following is recommended by Wunderlich as a convenient formula for its administration:

R Acidi salicylici, gr. xvi;
Ol. amygdalæ dulc., f3vj;
Acaciæ gummi, ʒiii;
Syrupi amygdalæ, f3viiss;
Aq. aurantii flor., ad f3iv.—M.

Salicylic acid is very little if at all absorbed through the skin.

ENORMOUS HYDROCELE SITUATED IN THE ABDOMEN CAUSED BY UNDESCENDED TESTICLE.—The following case is related in the *Lancet* for February 13: A man 28 years of age was admitted into the British Infirmary on account of a large prominent tumor measuring eight inches by eight inches, lying in the left side of the abdomen. The skin and external oblique muscles were in front, but it was evident that the mass of the abdominal parietes passed behind the tumor. Fluctuation of the consistence of serum was felt in all the tumor, save a solid portion at the lower part measuring two inches by two inches. The patient's history showed that his left testicle had never descended, but lay in the inguinal canal. Six years ago, having to walk a great deal, he began to feel pain in this testicle, which soon began to swell and attained a large size. Soft swelling of the parts above set in, and soon prevented him from walking, and gave him much pain. The tumor, therefore, was a hydrocele of the testicle. After drawing off the fluid with a trocar, a seton was introduced, the object being to set up free inflammation in the sac. The cavity became in due time contracted, but the testicle continued enlarged, and, in order to reduce this, liniment of iodide of potassium was applied, and the iodide given internally with favorable results.

AN UNUSUAL RESULT OF SEPTIC POISONING.—Under this title Dr. W. S. Bigelow (*Boston Medical and Surgical Journal*, March 11) gives notes of ten cases of a peculiar disease recently observed among newly-born children in the Boston Lying-in Hospital. The characteristic features were, discoloration of the skin, diphtheritic inflammation of some of the mucous surfaces

(in one case thrombo-phlebitis), hæmaturia, dark-green fetid dejections. Together with these symptoms there was found an alteration of the blood, consisting in—1, excess of white corpuscles; 2, alterations of red corpuscles; 3, the existence of granules. Accumulations of the amorphous material of the red corpuscles in the renal tubercles, with clots in some cases in the ureters and bladder. Accumulations of spores: 1, in the renal tubes, with extension outside their walls; 2, in the larynx, and possibly on the other surfaces affected by the diphtheritic process.

The process is generally endemic. The local accumulation of spores appears to be in close relation to the phenomena of the disease.

DIVISION OF POSTERIOR TIBIAL ARTERY TREATED BY COMPRESSION.—Dr. Edwardes Kerr reports the following case (*Lancet*, March 6): J. F., aged 50, a hay-trusser, was returning home from work with his large hay-trussing knife and three-pronged fork (weighing together about six pounds) slung over his shoulder upon the end of a stick. The strap by which they were attached to the stick gave way, and the point of the knife fell upon the right ankle, which was hindermost in the act of walking. Not knowing what mischief had occurred, he continued walking until he fainted, when his assistant, who was with him, thinking he had swooned from loss of blood, applied a strap firmly round the leg below the knee, and got him home as best he could. The patient was first seen by Dr. K. an hour later. Finding it utterly impracticable under all the circumstances to attempt to secure the artery (which spurted so soon as the strap was removed), he applied a graduated compress directly over and above the wound, put the patient to bed, and left him for the night. The bandage and compress was kept on for twenty-one days, and the patient in bed. At the end of the eighth day a small hole was made in the bandage for the exit of any matter which formed, and beyond that it was left entirely alone. On the twenty-first day Dr. K. removed everything, and found a wound three inches long, extending obliquely downwards and forwards below the inner malleolus, with a healthy granulating surface. No pulsation could be detected below the wound, and there was no hemorrhage from the day of the accident. The patient came down-stairs on the twenty-second day, and walked about his house with the aid of a stick, and, beyond feeling weak from loss of blood, complained of nothing.

PROLAPSE OF THE URETHRA SIMULATING PROLAPSUS UTERI.—The subject of this observation was a woman 55 years of age, who, after a prolonged walk, became sensible of the presence of a tumor between the labia of the vulva. Dr. Chamono, being called in, found, on examination, a tumor the size of a nut, having an opening in its centre, and presenting an almost perfect resemblance to the neck of the uterus in a multipara.

This tumor, which presented at the vulvar opening, had a certain consistence, and was sensitive to pressure; it could be replaced in the vagina, but immediately prolapsed when pressure was removed. Dr. C. thought at first that he had a case of prolapsus uteri to deal with, but on practising the vaginal touch he became aware that the cervix uteri occupied its normal position, and that he had a prolapse of the inflamed urethral mucous membrane under examination. Reduction was at first impossible; but rest in bed, with the use of astringents, finally enabled the operation to be performed successfully.—*Gaz. Méd. de Paris*, March 13; from *Anfiteatro Anatómico*.

A SOCIETY for the abolition of vivisection has been started in London: it is probably brother or sister to the Anti-vaccination League.

MISCELLANY.

CHEAP.—The Northern Ontario Medical Association is composed of men who are willing to work cheaply. So at least we infer from the following copy of the tariff of fees adopted by the Association, which we take from the *Canada Lancet*. Let us hope that rents and marketing are cheaper in Northern Ontario than they are in Philadelphia.

MEDICINE.

For Medical Advice in office, with or without medicine	From \$0.50 to \$1.50
" Visits in the Villages during the day	1.00
" " " " night	2.00
" " into the Country, one mile or less	1.00
" " " " each mile after the first	0.50
" " " " by night, one mile or less	2.00
" " " " per mile	0.75
" Consultation Visits, an extra fee of From \$1.00 to 2.00	
" Medical Certificates of any kind (mileage as above)	5.00
" Unusual detention, every hour after the first, by day	0.50
" Unusual detention, every hour after the first, by night	0.75

OBSTETRICS.

For ordinary cases, each (no complimentary visits after)	\$5.00
If more than five miles distant, mileage as above also to be charged.	
If instrumental cases, or those seriously complicated, as with Hemorrhage, Convulsions, etc.	10.00
Detention over six hours; per hour, in addition to above	0.50
Accounts to be furnished every three months.	

THE AMERICAN REVIVALISTS IN LONDON.—The *London Lancet*, in an editorial on the "Psychology of Revivals," writes as follows: "Emotion is the motive power on which, for the most part, our religious leaders have relied to stir men's minds, to effect what is termed, with more or less justice, their conversion. To effect this, much force is needed, and in those whose minds are in a condition of unstable equilibrium, the resulting perturbation is sufficient to disturb the normal balance of thought and feeling, and start a series of consequences which may result in pronounced insanity. That this is a frequent occurrence may be doubted. Religious delusions are common enough in the insane, but that probably arises from that region of thought and feeling presenting the most unobstructed field for excessive action.

"It is in periods of 'revivals,' when religious emotion is stirred in disproportionate degree, that the danger of such results is greatest; and this aspect of a movement so extensive as that now commenced in London comes fairly within the range of the physician's consideration. Judging, however, from personal observation, we should say that no movement of its extent could well present less danger of excessive or perverted emotional effects than that of Messrs. Moody and Sankey.

The testimony of most unprejudiced observers is to the same effect. The services are singularly free from the more objectionable elements of 'revival' meetings. Sympathetic but not overwrought music, and shrewd, rough aptness, sometimes humor, of the sermon, are the characteristics which mark the services from most ordinary preaching of the same theological school; and there is nothing to point to artificial stimulation of the emotions more than necessarily attends extempore worship and earnest preaching in a large concourse."

ORNAMENTAL PRESERVATION OF THE DEAD.—Some one writes to the editor of the *Lancet*, suggesting for the consideration of those interested in the question of interment the use of glass cases, tubular in form (the shape used for growing cucumbers); the smaller end of the tube completely closed, into which tube the body would be passed first, and then hermetically sealed above and beyond the head. The body, thus converted into a "vitreous mummy," might be retained in the house for a longer time, while friends would have the opportunity of viewing the body without detecting any offensive odor. These glass coffins might be made as handsome as any one desired. The wealthy could have them made colored and cut, like Bohemian vases; while for the poor the coarse stout glass used for skylights would not be much more expensive than wood lined with flannel, etc.

TRIAL OF A SURGEON FOR MANSLAUGHTER.—A surgeon named Peacock was recently tried at the Warwick Assizes for causing the death of a woman whom he attended in her confinement, by cutting away many feet of intestine which protruded through a rent in the vagina.

The sentence of the court was mitigated by the fact that the poor woman would in any case have died.

After an hour's deliberation, the jury returned a verdict of guilty, with a strong recommendation to mercy. Lord Coleridge said he entirely concurred with the finding, but, as there was an absence of all aggravating circumstances, the sentence would be six months' imprisonment without hard labor.

A HOMŒOPATHIC NOVEL.—An anonymous English author has endeavored to seduce the unwary reader into a consideration of homœopathic principles by presenting these in the framework of a very slight novel. The plot is said to turn upon the rejection of a hapless swain by his innamorata, on account of his having "gone over" to homœopathy. The work abounds in arguments between the unscrupulous advocates of regular practice and the chivalrous adherents of the "new views," in which the latter are, of course, invariably triumphant. The hero performs wonderful cures in all directions, and finally wins the fair. As a literary effort, the work may be said to be a "high dilution."

ABUSE OF TOBACCO IN AMERICA.—The average number of cigars smoked in the United States during each twenty-four hours is 5,168,000. The tobacco-users paid

through importers \$6,150,060.41 gold to the government last year in the shape of import duties, and \$33,242,875.62 through manufacturers, on account of taxes.—*Medical Press and Circular*.

An official return gives 1,295,529 kilogrammes as the amount of horse-flesh consumed in Paris during 1874. There are now fifty horse-flesh butchers in Paris itself, and five in the Banlieue.—*Medical Press and Circular*.

THE number of the *British Medical Journal* for March 20 contains a paper by Elizabeth Garrett Anderson, M.D.

DR. VON LUSCHKA, the famous anatomist, died on the 1st of March last.

THE death of Baroness Schuhaj, a noble Hungarian lady, at the age of 118, is announced.

NOTES AND QUERIES.

OBITUARY.

DEATH OF D. FRANCIS CONDIE, M.D.—Died, at his residence at Morton, Delaware County, Dr. D. Francis Condie, on March 31, in the eightieth year of his age. Dr. Condie was born in Philadelphia on the 12th of May, 1796, and was for many years one of our most prominent practitioners. He was also very widely and favorably known throughout the United States through his medical writings, especially by his work on the "Diseases of Children," which, at the time of its appearance, was one of the best, if not the best, in the language. The principal of his literary labors are the following: "An Abridgment of Thomas's Practice," 1817; "Course of Examination for Medical Students," 1824; "Catechism of Health," 1831; "Treatise on Epidemic Cholera," in conjunction with Dr. John Bell, 1832; "Diseases of Children," fourth edition, 8vo, 1854. Dr. Condie edited Dr. Fleetwood Churchill's works on the "Theory and Practice of Midwifery," and "Diseases of Women," and he made frequent and valuable contributions to the *American Cyclopædia of Practical Medicine and Surgery*; the *Philadelphia Journal of the Medical and Physical Sciences*; *North American Medical and Surgical Journal*; *Journal of Health, Philadelphia*; *American Journal of Medical Sciences*; *Transactions of the College of Physicians, of Philadelphia*; and to the *North American Medico-Chirurgical Review*.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

An aged and weighty lady has a fatty dilated heart, associated with valvular disease. I found her the other night in a state of collapse; no pulse, face blue, countenance shrunken, cold sweat, etc., etc. One inhalation of amyl nitrite restored her. It probably acted by unloading her heart in opening wider avenues for her blood.

MARCH 29, 1875.

Yours, etc.,

A. K. MINICH.

PENNSYLVANIA ASSOCIATION OF DENTAL SURGEONS.

DR. JAMES E. GARRETTSON will by invitation deliver a lecture before the Pennsylvania Association of Dental Surgeons on the evening of April 13, at the Pennsylvania Dental College, Tenth and Arch Streets. Subject, "Who and what is Man?" An invitation is extended to the members of the medical profession.

OFFICIAL LIST.

MEMORANDUM.

No changes in the stations and duties of officers of the Medical Department U.S. Army for the week ending April 5, 1875.

SATURDAY, APRIL 17, 1875.

ORIGINAL COMMUNICATIONS.

THE PHYSIOLOGICAL ACTION OF HEMLOCK AND ITS ALKALOID.

BY B. F. LAUTENBACH, M.D.

IN the following paper, an abstract of a prize essay for the degree of Doctor of Medicine in the University of Pennsylvania (the entire essay the author hopes to have shortly published in a different form), there will be presented conclusions based on a study of the papers of former investigators on conium, and on a careful analysis of one hundred and forty-eight experiments made by the writer.

Notwithstanding the labors of Kölliker, Guttman, Verigo, Harley, Pelvette and Martin-Damourette, the present state of our knowledge respecting the physiological action of conium may be summed up in the words of one who was one of the most eminent of modern therapeutists. About sixteen years ago, Pereira (Elem. Mat. Med., vol. ii.) wrote, "In the present state of uncertainty with respect to the real physiological operation of hemlock, it is obviously impossible to lay down indications or contraindications for its use, which can be much relied upon."

As conia represents the entire active principle of hemlock, I shall confine my remarks almost exclusively to it.

In man, the chief symptom produced when the alkaloid is given in doses just sufficient to impress the system decidedly, is great muscular weakness, accompanied by giddiness, and occasionally by disorder of vision. There is an intense desire to lie quiet in a semi-horizontal position, and, owing to the heaviness of the eyelids which now occurs, the eyes are half closed, thus giving rise to the impression that the person is asleep. On attempting to walk, his feet feel as though they did not belong to him, and he falls, his knees refusing him support. The pulse is at first increased and afterwards decreased in frequency. Sooner or later, as the drug impresses the system, the pupils dilate. In some persons these symptoms are accompanied, rarely preceded, by symptoms of gastro-intestinal irritation, nausea, and, rarely, vomiting. If the dose be a poisonous one, we have, in addition to these symptoms, total failure of voluntary movements and convulsions occurring (*vide* a case of poisoning by hemlock leaves reported by Dr. Bennett, *Edinburgh Medical and Surgical Journal*, 1845).

Physiological effects on vegetables.—Experiments by Marcet (*Ann. Chem. et Phys.*, xxix. 21, 9), Schübler and Zeller (*Schweiger's Journ. f. d. Chem.*, Bd. i. S. 54), and by the writer, have placed it beyond a doubt that the alcoholic extract of conium acts injuriously on plants; but, as in several other experiments the writer ascertained that the alkaloid conia, instead of acting injuriously on plants, really preserves them from decay, the poisonous effects of the hemlock extract must be due to impurities,

and not to the exceedingly small amount of conia present.

Local action.—A study of the local action of the drug shows that it causes a progressive loss of functional power in every highly-organized tissue with which it comes in contact. Nerve-centres, peripheral nerves, muscles, both striated and non-striated, all succumb to it alike. If such contact be not continued too long, the tissue may recover even after a total suppression of its functions,—a proof that the alkaloid exerts no destructive caustic influence upon the tissues, such as Van Praag (*Reil's Journ. f. Pharmacodynamik*, Heft i. S. 33) claims. Excluding the burning pain and the anæsthesia which follow it, the writer has never observed any action on the tongue, even if the alkaloid was placed on this most sensitive organ undiluted.

Action on the brain.—Conium is not a hypnotic, though it may possibly cause the brain to become slightly clouded, but not to the extent to produce unconsciousness. In inducing complete repose of the muscular system, conia powerfully predisposes the brain for sleep,—brings sleep within its reach, so to speak, but there leaves it. If the imagination should happen to be dull, the brain may accept the invitation, and sleep occur.

Convulsions were early mentioned as symptoms of poisoning by hemlock; but the cause of these convulsions had never been determined. Christison (*Trans. Roy. Soc. Ed.*, xiii. p. 383) imagined them to be due to a depressing action on the spinal marrow, while Damourette and Pelvette (*Gaz. Méd. de Paris*, 37, 1870) attributed them to excitation of the cord.

Convulsions can be produced by a drug in but five different ways: first, they may be muscular; second, they may be due to irritation of the periphery of the efferent nerves; third, they may be caused by irritation of the peripheral ends of the afferent nerves; fourth, they may be spinal; fifth, they may be cerebral.

That the convulsions of conia-poisoning are not due to irritation of the peripheral motor or sensory nerves, nor to any action on the muscles, was determined, first, by tying the abdominal aorta of various animals previous to injecting the conia, when, notwithstanding the cutting off of the poison from the posterior portions of the body, convulsions occurred uniformly over the whole body; secondly, by injecting conia into the amputated leg of a cat, when not the slightest evidence of spasm was observable.

That the convulsions are cerebral, and not spinal, was determined by the result of a number of experiments in which the spinal cord was cut previous to injecting the conia, when it was found that convulsions occurred in those portions of the body whose nerves were still in communication with the brain, but failed to occur in those portions of the body whose nervous communication with the brain had been destroyed.

Action on the spinal cord.—To determine this action of the drug, the writer made thirty-four experiments, two of which will now be given in full.

Exp. XVII.—On a large frog. Tied all the blood-vessels of the left posterior extremity, carefully excluding the nerves. The weakest current that would cause reflex movements in the injured limb was then determined.

3.58.—Injected one-eighth drop of conia.

3.59.—Acetic acid applied; causes no reflex movements in ligatured limb (previous to the injection it caused movements in one second).

4.01.—It takes the strongest current to produce reflex movements in the ligatured limb.

Exp. XVIII.—Tied all the blood-vessels of the left posterior extremities of a large frog, and then determined the weakest current which would cause reflex movements in the ligatured limb.

4.15.—Injected one-eighth drop of conia.

4.16½.—A much stronger current is required to produce reflex movements in the ligatured limb.

4.20.—The strongest current applied to the ligatured limb will not cause reflex movements.

As the ligatured limbs in these experiments failed to respond to irritants when the access of the drug to the trunks and periphery of the nerves was prevented, this failure must have been due to paresis of the spinal marrow, and not to any direct action on the afferent or efferent nerves. It is therefore proven that there is a steadily progressive stage of spinal depression, with no preceding stage of spinal excitement.

Action on the peripheral efferent nerves.—To discuss this subject is really to discuss what has long been considered, and beyond a doubt is, the chief symptom of conia-poisoning, namely, paralysis. Christison (*loc. cit.*), Reuling and Saltzer (*Deuts. Klin.*, 1853, No. 40), and Van Praag (*loc. cit.*) attribute the paralysis to the action on the spinal cord; while Albers (*Deuts. Klin.*, 1853, No. 34) believes that the paralysis was cerebral.

The first investigator who threw any real light on the subject was Kölliker (*Virchow's Archiv*, Bd. x. S. 228). In 1856 this distinguished investigator announced that the failure of motion in conia-poisoning is due to a direct action upon the periphery of the efferent or motor nerves. He first experimentally determined that in frogs killed by conia the application of the galvanic current to a nerve fails to induce contractions in the tributary muscles. He then cut off the supply of blood to the hind extremities, and found that after voluntary motion had ceased anteriorly, and even after galvanic irritation of the anterior nerves had lost its influence upon the muscles directly supplied by these nerves, irritation of the same anterior nerves caused reflex contractions in the hind legs, thus showing that the anterior afferent nerves and the spinal cord still retained functional activity after the loss of it in all those efferent nerves reached by the poison. He then extended his experiments by severing in a frog all the tissues at the upper part of the thigh, except the nerve, and found that when an animal so prepared was poisoned by conia, after the paralysis was complete in all the extremities to which the poison had access,—after stimulation of the poisoned nerves failed to excite contraction in the tributary muscles,—the leg which had been protected from the action of conia responded not

only to irritation applied to its nerve, but also to stimuli placed upon distant portions of the body. After repeating these experiments several times, he drew the conclusion previously given.

His results have been confirmed by Guttman (Reil, Mat. Med. d. Chem. Pflanzenstoffe), by Verigo (*Deuts. Zeitschrift f. Arzneykunde*, xxviii. 2, 1870), and by the writer in a large number of experiments. They have been denied by Dyce-Brown and Davidson (*Med. Times and Gaz.*, July, 1870), they basing their denial on two experiments in which they obtained results directly opposing those of the other experimenters; but their experiments can be readily explained by an anomalous distribution of the iliac arteries which frequently is seen in lower animals.

Recently, upon the foundation of a simple, crude, and inconclusive experiment, Harley (Old Vegetable Neurotics, p. 11) has readvanced the opinion formerly held by Albers, that conia affects chiefly the corpora striata and the other centres at the base of the brain supposed to mediate between the will and the spinal cord; he attempts on this supposition to explain the paralysis. After studying his experiments and conclusions most thoroughly, one cannot help wondering at the fact of so eminent a physiologist and therapist drawing such an unwarrantable conclusion.

After studying the papers of the preceding investigators, it will be seen that the cause of the paralysis is still somewhat undecided. Paralysis can be produced by a drug in four different ways: first, it may be cerebral; second, it may be due to spinal paralysis; third, it may be due to direct action on the muscles; fourth, it may be due to paralysis of the peripheral ends of the efferent nerves.

That the paralysis of conia-poisoning is not muscular is proved by the circumstance that muscles taken from animals completely paralyzed by conia—paralyzed to such an extent that galvanic irritation through the nerves fails to excite contractions—can be made to contract most energetically when the galvanic current is applied directly to the muscles.

In fifty-one experiments made by the writer on dogs, cats, mice, and frogs, the main blood-vessels supplying one or both posterior extremities were tied before injecting conia, and in all but two of these experiments the limbs protected from the drug's action were not paralyzed until just before the occurrence of death, thus proving that the paralysis must have been peripheral. Had it been cerebral or spinal, the paralysis would have occurred uniformly over the whole body, notwithstanding the ligature of the blood-vessels. The same action was demonstrated when conia and strychnia were injected simultaneously into the abdomen of frogs from whose posterior extremities the direct access of the poison had been cut off. By their conjoint action there was produced a commingling of paralysis in all other parts of the body, with violent tetanic spasms in the protected limbs. This commingling would have been impossible if the paralysis were due to any action on the spinal cord or on the brain, and it can be explained only on the supposition

that conia paralyzes all the motor nerves with which it comes in contact.

Two experiments on young cats gave very exceptional results, which the writer is unable to explain except on the supposition that conia has a double action on the motor nervous system,—a paralyzing action on the peripheral ends of the efferent nerves, and a depressing action on the spinal motor tract. In almost all cases the former occurs first and predominates, the spinal paralysis not occurring until the period of death; yet in a few instances the former does not occur, while the latter becomes more marked.

Action on the peripheral afferent nerves.—Except the loss of irritability of the eyes, the sensory nervous system has always been supposed to remain unaffected. In some of the earlier experiments evidences were seen which threw doubt on this supposition, but later, when a number of experiments were made especially to determine this point, these doubts became certainties. These experiments proved that not only is sensation impaired, but that this impairment is due to paresis of the periphery of the afferent nerves.

In opposition to these conclusions could be cited all investigators on conia since the time of Christison; but, as I have yet to find the first paper in which efforts have been made to prove that loss of sensation does not occur, little importance can be attached to such assertions.

Action on the circulatory system—pulse.—In ordinary therapeutic doses, conia causes an increase in the number of heart-beats, which is followed by a decrease to the original number of pulsations. In poisonous and even in very full therapeutic doses the subsequent decrease is much greater than the primary increase. As no increase in the number of heart-beats occurred when the pneumogastrics were cut previous to giving the conia, the primary increase must have been due to paresis or paralysis of the pneumogastric centres. The subsequent diminution in the number of pulsations can be best explained by the occurrence of paresis of the vaso-motor nerves, due to commencing paralysis of the spinal cord.

Arterial pressure.—Conia causes the column of mercury in the cardiometer to be decidedly lowered at first, but very soon the mercury rises to far above its original height.

Action on the respiratory system.—The first effect of a poisonous dose of conia is to cause an increase in the number of respiratory movements; this is followed by a diminution, and ultimately, if the dose be sufficiently large, by their complete cessation. As the primary acceleration does not occur when both vagi have previously been divided, the acceleration must be due to an action on the pneumogastrics.

The failure in the respiratory movements advancing *pari passu* with the paresis of the voluntary muscle—general paralysis and the cessation of all respiratory movements occurring at the same time—renders it very probable that the diminution in the respiratory movements is due to the same cause as the paresis of the voluntary muscles.

Gastro-intestinal action.—In ordinary medicinal

doses no gastro-intestinal symptoms occur in man; in some experiments made by the writer, grain doses did not produce the slightest nausea, or even anorexia. In dogs, who vomit readily, this symptom almost always occurred, even if the drug was given hypodermically, proving that the gastro-intestinal irritation is not due to any local action on the alimentary canal, but that it is due to a specific action on the gastro-intestinal apparatus.

These symptoms are not exclusively canine, as attempts at vomiting are recorded by Bennett (*loc. cit.*) in a case of fatal poisoning by hemlock-leaves; and Schroff (*Vierteljahrsschr. f. Praktische Heilkunde*, 1855), in his experiments on the human subject, records one case in which vomiting occurred.

Action on the glandular system.—One of the first effects of a large dose of conia, in about one-half of the experiments, was to increase the secretion of the salivary glands. As this increase occurred when conia was injected into a vein or into the peritoneum, it cannot be due to any local action, but must be due to stimulation of the chorda tympani and other nerves concerned in the secretion of saliva.

Conia has no influence on the quantity or quality of the urine, nor has it any influence on the function of the skin. Its action on the biliary secretion has not yet been determined, but the circumstance that after death from conia-poisoning the gall-bladder is always found distended with bile, renders it probable that it increases the flow of bile.

Action on the muscular system.—The voluntary muscles escape unscathed in conia-poisoning, they continuing to respond to galvanism for a considerable period after death. The contractility of the muscles, however, may be destroyed by soaking in a concentrated solution of the alkaloid; but before such an effect can be produced in life the animal will have perished.

On the non-striated muscular fibres the action of the drug is more pronounced. Geiger (*Mag. f. Phar.*, Bd. xxxv. S. 72, 256) states that it produces irritation of the muscular fibres of the diaphragm and alimentary canal, while in the experiments made by the writer, contractions of the muscular fibres of the intestinal canal and bladder occurred.

Action on the pupil.—Dr. Hoppe (*Die Nervenwirkung d. Heilmittel*, Leipzig, Hft. 1) made a number of experiments to determine this action of the drug, and, in conclusion, says that in the beginning the pupil is contracted, but later it becomes very much dilated. His conclusion has been confirmed by Pelvette and Damourette (*loc. cit.*), who attribute the contraction to "augmentation of the excitability of the spinal cord;" but, as the contraction occurs only when conia is locally applied to the eye, it must be due to irritation, and to no general action whatsoever. The dilatation which is always produced when conia is absorbed is due to the paresis of the peripheral extremities of the motor oculi nerves no longer enabling the sphincter of the iris to counteract the radiating fibres supplied by the more slowly paralyzing sympathetic nerve.

Action on the temperature.—All investigators of conia have thus far almost totally ignored this action of the drug, and, so far as I am aware, until this

investigation no one has ever imagined that conia was so peculiar in its action as to be one of three drugs that decidedly increase the temperature of the animals poisoned. This increase occurs not only from poisonous doses, but also when ordinary therapeutic doses are given: *e.g.*, in the human subject one-seventh of a grain of conia caused the temperature to rise from 97° to $99\frac{1}{2}^{\circ}$. This increase in temperature lasts from three-fourths of an hour to an hour and a half, when the temperature gradually becomes normal.

Action on the sexual organs.—The genital depression attributed to conium by the ancients, modern investigators have been unable to discover. The ancients believed that not only did it repress sexual desire, but that it actually caused an atrophy of the testes and mammæ, which latter of course implies atrophy of the ovaries also. The utter falsity of this belief was shown in several cases of chorea occurring in girls about the age of puberty, in whom menstruation came on while they were under the physiological effects of conia.

While conia has no effect on natural sexual desire, morbid states are said to be much influenced by it. In proof of this Dr. Harley (*loc. cit.*) writes, "In those states of exhaustion and irritability which arise from self-abuse, and in those cases of erotic tendency that arise from some obscure irritation of the lumbar portion of the cord, I have never known conium to fail to give relief." This relief is better explained, however, by referring it to the depressant action which the drug has on the spinal cord than to any possible action on the sexual organs.

Absorption and elimination.—That conia is absorbed is beyond question, as it has been found by Orfila in the spleen, kidneys, and lungs of poisoned animals. The drug probably undergoes no change in the system, although Harley says it does because he failed to find it in the urine of an animal poisoned by hemlock; yet it is eliminated by the kidneys, in whose secretion Zaliski and Draggendorf found abundance of it in the first twelve hours of the poisoning, and traces of it for two days and a half.

That it is not necessary for conia to be changed in the system in order to produce the most marked action—that on the periphery of the efferent nerves—was proved by the following experiment:

Exp. LXXVIII.—Cut off both hind legs of a cat just killed with chloroform; both sciatic nerves respond equally to galvanism. Into the left femoral artery a one-grain solution of conia, while into the right an equal quantity of water, was injected. In thirty seconds the application of the galvanic current to the left sciatic nerve causes no response, while its application to the right sciatic causes contractions in its tributary muscles.

MURIATED TINCTURE OF IRON A CURE FOR NASAL POLYPI.

WITH A CASE.

BY GEORGE TROUP MAXWELL, M.D.,

New Castle, Delaware.

I DESIRE to recall the attention of the profession to an efficient mode of treating nasal polypi, which has not received the favor that, in my

opinion, it is entitled to, and which has, therefore, suffered unmerited neglect.

Without intending or desiring to exaggerate the danger, pain, and loss of blood caused by the operation almost universally practised for the removal of nasal polypi, namely, evulsion,—for I know that they are usually inconsiderable,—I nevertheless confidently assert that it has terrors for the subjects of the malady, and that many who are thus afflicted are deterred thereby from obtaining desired relief. Therefore, in this fact—that it presents itself in a less "questionable shape" to the instincts of a patient—is a potent reason in favor of the treatment of nasal polypi with muriated tincture of iron; and when its efficiency as a *radical cure* is guaranteed "the argument is exhausted," almost.

If it be true, as I believe, that nasal polypi (and here I desire to say that my experience is limited to the common or gelatinoid variety) can be removed by the use of muriated tincture of iron, *certainly and expeditiously*, there is an additional strong reason for its employment; which is, that the tendency to repullulation of the polyps can be thus effectually checked, and their reproduction prevented. All surgeons know, and all writers upon the subject admit, the frequency with which such growths are reproduced, after evulsion; but by occasionally inspecting the nares, successive polyps can be easily aborted upon their earliest appearance, by the application of the iron tincture.

The cure of nasal polypi by the employment of muriated tincture of iron was recommended first by Dr. J. H. Reeder, of Lacon, Illinois, who reported two successful cases in the *Chicago Medical Journal* for September, 1859. In 1867 I published a short article corroborative of Dr. Reeder's statements and experience, in the *St. Louis Medical Reporter*, in which the details of three successful cases were given. That article was reprinted in Paris. So far as my information extends, these papers comprise the whole literature of this subject. The profession did not derive from them a full appreciation of the importance of the subject, and, in consequence, a valuable suggestion has been permitted to languish from neglect.

That too little interest in the matter has been awakened is to be inferred from the fact that, in his "System of Surgery," Prof. Gross simply mentions Dr. Reeder's suggestion, and speaks of the mode of treatment—which he had not tried—as a "waste of time;" and, also, because Dr. J. Solis Cohen, in his admirable "Lectures on the Surgery of the Nares, etc.," published in this journal in 1873, neglects to make any reference to the subject. To a letter which I addressed to Dr. Cohen, subsequently to the publication of those lectures, he replied that he had never used the tincture of iron for the cure of nasal polypi, but would give it a trial.

But now to the case:

T. D., carpenter, aged 56 years, came to me to be treated for nasal polypi on the 26th of November last. His general health was good, but he had not breathed through his nostrils, or perceived odors, for over thirty years. The nares were completely closed and impacted

with gelatinoid polypi, which always produced a feeling of discomfort, and sometimes considerable pain. The distention was at times very great, and caused some disfiguration. He had used blood-root and a number of other astringents without effect, but had never been able to summon the courage required to submit to the operation of evulsion. I injected about a drachm of the tincture of iron, reduced in strength one-half by admixture with water, into each nostril, holding his head back so as to retain the fluid in contact with the polyp a few seconds. This simple operation was repeated daily, and on the third day the masses began to slough and to be discharged. At the end of a week their destruction seemed to be complete; the nares were pervious, and the sense of smell was recovered.

The treatment of this case was more protracted than any I had before encountered, three or four days being sufficient hitherto. The delay in this case I attribute to the impacted condition of the nostrils, which prevented access of the tincture to any but a limited portion of the body of the polyp. As soon as the fluid gains access to the pedicle, the cure is rapid, because the death of the polyp is quickly effected. In this case the injection was repeated the third or fourth time before the fluid could pass through the posterior nares into the pharynx. The irritation of the nares caused by the dilute tincture is trifling in severity, and of short duration. Mr. D. discharged the duties of his vocation, without interruption, whilst the treatment of his case was in progress.

AN ADDENDUM TO AN ARTICLE ON AN "OBJECTIVE NOISE IN THE EAR," ETC.

BY CHARLES H. BURNETT, M.D.

IN No. 172, current volume of the *Philadelphia Medical Times*, I presented an account of an objective noise in the ear of a Japanese. As the patient expressed little or no desire to be relieved of the noise, I had an opportunity of watching any other phenomena connected with this singular case.

On February 6, the patient informed me that since he had visited me last, a few days previous, a perforation had occurred in the membrana tympani of the ear in which the snappings had been heard, and that the peculiar noises had nearly ceased.

I found, indeed, a perfectly well-defined dry perforation in the antero-superior quadrant of the membrana tympani where I had previously observed the spasmodic retraction of the membrane, but there was no explanation of the perforation so far as I could discern, and the patient could furnish no solution of its occurrence.

The snappings had become nearly inaudible and very infrequent, and in a few days entirely disappeared. Although a little discharge ensued in about a week after the perforation, probably from the exposure of the mucous lining of the tympanic cavity to the winter atmosphere, it was easily checked, and the membrana tympani closed. Since then there has been no return of the snapping noise, nor any spasmodic motion in the velum palati, Eustachian tube, middle ear, or membrana tympani.

The natural history of this case is suggestive of a possible treatment in similar cases, when the noises occurring in an ear with intact membrane cause such a degree of annoyance to the patient that some effort towards relief is demanded of the surgeon. I would therefore venture to suggest that it might be well to perforate artificially the membrana tympani in such a case, for we have seen that almost immediate relief was given by a natural perforation of the membrana tympani in the Japanese case.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

CLINIC OF DR. R. J. LEVIS.

Reported by JOHN B. ROBERTS, M.D.

EXCISION OF A LARGE VASCULAR TUMOR OF THE FACE IN A CHILD.

A MALE child, aged two and a half years, presents an immense tumor, involving the entire cheek and lower lip upon the right side, and projecting into the cavity of the mouth. At his birth it was the size of a hen's egg, but by continuously increasing it has now attained a great bulk, forming a pendulous mass, extending backward from the middle of the lip, and bulging about four inches forwards. The inferior maxilla has become deformed, and the teeth displaced, by the pressure and dragging of the tumor; and it projects so much into the cavity of the mouth that it is almost impossible for the patient to put the teeth of the two jaws in contact, and he has therefore been obliged to subsist almost exclusively on a fluid diet.

The tumor is painless, soft to the touch, its surface purplish in color; and the slightest scratch upon it is followed by copious hemorrhage, from the recurrence of which the child has at several times almost perished.

All these points render the diagnosis clear, and prove the tumor to be a nœvoid growth, or hypertrophied condition of the capillary vessels, which must be removed if the patient is to have any chance for his life, since it is rapidly growing, and the occurrence of uncontrollable hemorrhage may cause his death at any time.

Nœvoid tumors are usually congenital, and their most common site is upon the head and face, though they may occur anywhere, since they are pathologically merely a hypertrophy of the capillary arteries and veins; in some cases the arterial, in others the venous element predominating. They may increase in size

until they, as in the present instance, attain an enormous bulk; they are also temporarily enlarged and made more turgid by crying or any exertion on the part of the patient which increases the intravascular blood-pressure.

The location of vascular tumors is generally in the subcutaneous connective tissue or the skin, so that they are entirely covered by healthy integument, or, as is more frequently the case, the vessels of the skin are blended with the tumor, and an appearance of vascularity is evident, especially at the most prominent part of the tumor. These tumors becoming ulcerated, hemorrhage may supervene, which, if profuse, may jeopardize the life of the patient. In some cases when they have been allowed to remain until adult life in females, they have been the seat of vicarious hemorrhage at each catamenial period.

In this case the tumor is probably, like most nævoid developments of childhood, a mass of tortuous veins, which are varicose and cavernous. The term aneurism by anastomosis has been applied to nævoid tumors, but especially to those with a decided predominance of the arterial element, and in which pulsation, synchronous with the heart, is often evident.

Vascular tumors when superficial can scarcely be confounded with other growths, for the pulsation, the more or less complete emptying under pressure, and the increase in size during excitement or when held downward so that the blood gravitates into them, are sufficiently characteristic. When located in the deeper structures, however, the evidences may be masked and very obscure, so that a positive diagnosis may be exceedingly difficult.

The usual treatment is to transfix the nævus with pins, around which a ligature is wrapped, and the growth thereby strangulated and allowed to slough; or excision may be practised in order to remove the angioma, which method, however, is generally accompanied by a good deal of bleeding. In this case the size of the mass renders it inadvisable to attempt strangulation, and therefore it shall be excised, after hemorrhage has been guarded against by thrusting a number of long acupuncture-needles through the tissues around its base, so as to cut off the entire blood-supply. It would hardly be possible to extirpate the mass by keeping the knife entirely in the surrounding healthy tissue, and if the least portion of the angioma remain it would bleed profusely from the cut surface. Hence it is better to apply acupuncture at the base of the tumor to all the afferent vessels before commencing the operation of excision. The first long acupuncture-pin is entered at the angle of the jaw, and pushed forward along the bone, to control the facial artery, which has been dragged somewhat out of position; the coronary is next compressed in a similar manner; and so a half-dozen long pins are thrust through, thus circumscribing the base of the tumor, and overlapping each other somewhat, in order to guard every point. Strong cords are then wrapped around the needles, including the base of the tumor, to render it still more safe, since the child, enfeebled by previous hemorrhages from the surface of the growth, can ill afford to lose any blood during the operation.

The knife is now carried around within the line of the circumscribing pins, and the mass, consisting of a network of hypertrophied vessels, removed. The tumor now looks quite collapsed and shrunken, for the blood has all flowed out of the spongy mass. There will be no attempt made to draw the edges of the large, gaping wound together, and of course the acupuncture-needles shall remain for a day, or longer, unless there be appearance of sphacelation caused by them. The dressing shall consist of the carbolic oil so much used in this hospital. * * * * *

The patient, after having continued for almost a week

in a favorable condition, began to show signs of exhaustion, probably due to the imperfect manner in which he had been for a long time fed on merely weak fluid nourishment. He finally became unable to take proper and sufficient food, and soon died, exhausted.

TRANSLATIONS.

SEROUS OVARIAN CYSTS.—At a recent meeting of the *Académie de Médecine*, Dr. Panas read a paper on this subject. His conclusions are as follows:

1. Among the cysts called ovarian, there is a class of unilocular cysts containing a special fluid, the treatment of which is as simple as it is certain in its results.

2. The characters of the cystic fluid are: complete absence of viscosity; perfect diaphaneity (with occasional exceptions); poverty in proteinous material (modified albumen); and its relative richness in alkaline salts, principally chloride of sodium. Slightly or not at all precipitated by heat and nitric acid, the liquid in question is precipitated by alcohol. In this respect this fluid bears a certain analogy to that found in the spermatic cysts of men, as we may be convinced by comparison of the two fluids.

3. We are at present ignorant as to whether the point of origin of these cysts is actually in the ovary or is not rather in the *parovarium* (body of Rosenmüller).

4. The treatment of these cysts is still more simple than that suggested by Boinet, who proposed puncture by means of a trocar, followed by injection of iodine. A simple puncture by the trocar is sufficient to bring about a cure, by removing the fluid completely or even partially.

5. By this process not only is all danger avoided, but even the slightest pain to the patient. In a word, the treatment of these cysts is easier than that of simple or spermatic hydrocele in men, which requires, almost always, the subsequent employment of caustic or strongly irritating injections.—*Le Mouvement Médical*, March 13. X.

COMPARATIVE VALUE OF CARBOLIC AND SALICYLIC ACIDS IN DIABETES.—Ebstein and Müller continue (*Berliner Klin. Wochens.*, No. 5, 1875) their researches upon the action of carbolic acid in diabetes mellitus, and add some observations upon the use of salicylic acid in the same disease. They believe that in certain cases of this disease carbolic acid diminishes the proportion of sugar in the urine, together with the various other diabetic symptoms. These cases are probably those which are connected with obesity, and where an anti-diabetic diet is apt to do good.

Carbolic acid is particularly useful in the lighter cases,—those in which the Carlsbad cure does so much good. It does not, however, any more than the latter, protect against relapses; and, indeed, it fails in some cases when this does well.

Salicylic acid seems to be quite powerless for good in diabetes mellitus; although it is less disagreeable to take, yet many patients actually prefer carbolic acid. The latter may be administered in doses of one centigramme or more. It rarely disagrees; in one case occasional burning pain in the œsophagus was noticed. It in no way disturbs the stomach. X.

VICES OF CONFORMATION IN THE ANUS.—Dr. Delens communicates the two following cases to the *Bulletin Gén. de Thérap.*, March 13: In September, 1874, he was called to see a little boy, four years of age, in whom two anal openings were made out, situated on either side of the median line, and separated by a cutaneous band; only the right was perforated, and communi-

cated with the rectum. The median septum was excised, and the two ani united into one. This abnormal conformation gave rise to no inconvenience in defecation. The second case was that of an infant, not forty-eight hours old, and who presented an imperforation of the rectum; the anus was well formed exteriorly. The operation was immediately performed; in order to get at the bottom of the cul-de-sac more easily, resection of the coccyx was performed. At present this little patient, who is six months old, has a prolapse of the rectum. Perhaps this prolapse is due to the resection of the osseous appendage. It should be noted that the infant lived under very unfavorable conditions.

X.

EPILEPTIFORM ATTACKS FOLLOWING PARAPHIMOSIS (*Wien. Med. Presse*, March 7).—Dr. Moritz Werthur reports the case of a healthy boy, 15 years of age, in whom a severe paraphimosis had been brought about, in all probability, by attempts at onanism. When first seen, the swelling of the parts would not allow manual reduction. After the administration of an anæsthetic, a slight incision was made to relieve tension in the œdematous tissue, and the paraphimosis was reduced. A dressing of cold-water cloths was used, together with a bit of charpie moistened with dilute solution of carbolic acid placed between the prepuce and the glans. The parts recovered their natural condition within three days, but at the end of that time the patient was seized with frequent and severe epileptic convulsions. Suspecting psychical causes, since nothing could be observed to account for the trouble so far as the lately-affected parts were concerned, Dr. W. made use of the oxide of zinc in repeated doses, in connection also with diminishing amounts of morphia. The attacks ceased within a week, and for two years, up to the date of the communication, had not returned. Dr. W. adduces, as confirmatory of the benefit of this drug, the case of a pregnant woman attacked by epilepsy, who, after trying various remedies in vain, was quickly cured by the use of valerianate of zinc and morphia.

X.

CAUSES AND SIGNIFICATION OF SUBSCAPULAR FRICTION.—Under this title Dr. Terrillon (*Archives de Méd.*, 1874) calls attention to a peculiar crepitation produced by movements of the scapula over the chest-walls in spare persons, and in patients who suffer from ankylosis of the shoulder.

The contact of the two osseous surfaces rubbing one over the other causes the formation of a serous sac. This presents a special pathology with which it is necessary that the physician should be acquainted. Dr. Terrillon, in his communication to the *Archives*, treats of inflammations, abscesses, hygromata, cysts containing rice-like particles, etc., as occurring in connection with this serous sac.—*Le Progrès Méd.*, February 6.

X.

DERMOID CYST OF THE OVARY.—M. Terrier communicates the following observation. It concerns a patient coming under his care for a voluminous tumor occupying the right iliac fossa and presenting all the characters of an ovarian cyst.

An exploratory puncture revealed the existence in this tumor of epithelial cells, of hair, and of a thin grayish-white liquid. An operation was decided upon, and was accomplished without difficulty. The results were favorable. The temperature never rose above 100.5° F. Retention of urine supervened without appreciable cause, but disappeared at the end of five days. Histological examination of the sac showed that it presented on its internal aspect the appearance of skin. In fact, hair, fatty granules, sudoriferous glands, etc., were found.—*Bull. Gén. de Thérap.*, March 15.

THERAPEUTIC NOTES.

LIQUID GLYCERIN FOR BURNS.—

R Calcis oxid., gr. iii;
Spirit. chloroformi, gr. iii;
Glycerinæ, f3iiss.—M.

Charpie is dipped in the mixture, and placed over the burned surface; it is then covered with a thin sheet of gutta-percha, and the whole surrounded with a loose bandage. It is important that the charpie should be closely applied to the entire burned surface. The pain ceases almost instantly, and the sore heals very rapidly.—*Trans. N. Y. Med. Jour.*

WORMS.—

R Santonini, gr. iii;
Sacch. alb., q. s.

M.—Ft. in chart. no. iii.

For a child of two and a half years one of these powders may be given at bedtime for three days, the food in the mean time being soups and broths in small quantity. On the morning of the fourth day a dose of calomel and jalap may be given; subsequently a tonic.

TREATMENT OF PERTUSSIS BY INHALATION.—

R Ext. belladonnæ, M v ad x;
Potass. bromid., ℥i;
Ammon. bromid., ℥ii;
Aque, f3ii.—M.

Inhale one tablespoonful in the ordinary steam atomizer; or this amount may be diluted by filling up the glass with water. In severe cases this may be used twice daily, until the urgency of the symptoms is relieved, and then continue once daily until the cough has entirely disappeared.—*Boston Med. and Surg. Jour.*

PROLAPSUS ANI TREATED BY ERGOTIN.—Von Langenbeck is said to treat prolapsus ani with astonishing success by hypodermic injections of a solution of ergotin (five to fifteen parts in one hundred of water). He replaces the bowel, and, inserting the point of the syringe about an inch deep into the cellular tissue, throws in from one to two grains of ergotin. This should be repeated every three or four days for several weeks, hardened fecal masses having been first removed by injection.—*Medical Press.*

COLLODION AND MORPHINE IN SHINGLES.—After exhausting all the methods advised for the treatment of shingles, and especially the atrocious pains which attend this disease, Dr. Bourdon adopted the following. A stratum of morphinated collodion (collodion 30 grammes, muriate of morphia 50 centigrammes) was applied to the diseased parts without opening the vesicles. The pain ceased on the second day, and after seven or eight days, when the pellicle fell off, the vesicles had entirely disappeared, and only a slight redness was apparent.—*Gaz. Med. Ital.*

INJECTION IN BLENNORRHAGIA.—

R Potass. bromid., ℥iss;
Glycerinæ, ℥iii;
Aq. destillat., ℥iv.—M.

Inject every four hours, bromide of potassium being administered at the same time internally. This injection may not only be used in the chronic but also in the acute stage of the disorder. When the disease approaches the end of its course, an astringent may be added to this solution. Abstinence from beer and stimulating food is advisable.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, APRIL 17, 1875.

EDITORIAL.

PRINCIPLES AND STATISTICS IN HOSPITALISM.

THERE are two distinct methods of solving the various practical questions which arise in our every-day professional life: one, the application of principles, the other, the use of statistics. Each of these methods may lead to false results, because human nature is weak and fallible. Principles as seen by any one mind are simply the conceptions, original or acquired, of that mind, and may be as devoid of truth as a fool is of wisdom. Further, even if these principles, *i.e.*, the premises, be correct, the application, *i.e.*, the assumed sequence, may be as illogical as the average human intellect. To enumerate the loopholes by which error may creep into statistical arguments would be as hopeless a task as to attempt to count human failures in observation or statement.

These things being so, it seems to us that only by the free use of both methods, and the correcting of one by the other, can truth be arrived at.

It appears to us a fixed principle that absolute freedom to the air affords the best possible ventilation; that no artificial means can ventilate any large apartment so thoroughly as nature ventilates the single tree-top of the open prairie. If this principle be true, it appears logical that the nearer any apartment in its conditions approximates to the open air the better ventilation it will have. A simple roof raised upon high distant iron pillars ought to afford, so far as ventilation is concerned, the best possible form of a

ward, and, we believe, in a warm climate it would yield the best surgical results. No statistics have ever seemed to us necessary to determine that an open tent, if it can be well warmed, offers a better chance than any surgical ward to those who are so unfortunate as to undergo serious operations. Carrying out this same line of argument, it seems a natural conclusion that the best summer ventilation in an ordinary hospital is to be obtained by having an abundance of windows and keeping them always wide open.

Holding these views, we naturally were somewhat surprised by the following paragraph, from the first paper in the current number of the *American Journal of the Medical Sciences*:

"Of the total number of deaths after amputations during forty-five years, we find that the mortality of the different months of these years was as follows:

January, 11 died.	July, 29 died.
February, 15 "	August, 22 "
March, 15 "	September, 19 "
April, 16 "	October, 21 "
May, 27 "	November, 11 "
June, 25 "	December, 19 "

"It will be observed that the smallest number of deaths occurred in January and November, when the hospital wards have pure but heated air by forced ventilation, while in the months of May, June, July, and August, when the ventilation in the hospital is effected by simply opening windows, we find the largest number of deaths. Mr. Edward Richardson has examined the hospital records, and has found that during a period of twenty-five years, from 1850 to 1874, inclusive, in 2015 deaths in the surgical wards, the months of February and November also exhibit the smallest number; from May to September the mortality was very much greater; while in July and August the deaths were double the number of those in February. These results may be induced by various agencies, but they naturally suggest the subject of ventilation in the summer in hospital wards, and whether proper change in the air of a ward can be brought about without open fireplaces or currents of air forced from a fan. It is well known that opening all the windows of a ward in certain states of the atmosphere will not change the air at all, and there is little doubt that either of the above-mentioned plans to secure ventilation might be adopted with much better results."

The more the conclusions reached in this paragraph are thought over, the more definitely does it appear that either the principle which we have brought forward or else the statistics just detailed are at fault. Not being able to find any incorrectness in the principles, we have naturally been led to examine the statistics. We have not access to the records of the Hospital, but Dr. Morton in the

earlier portion of his paper gives a chronological table of all the operations performed in the hospital during the years 1870, '71, '72, '73, and '74. Rearranging this list, so that it shall show the number of operations per month, *præsto*, the number of deaths is greater in July than in January *because* there are *more cases*; the mortality *per cent.* is greatly less in the summer than in the winter months. This is the list:

WINTER MONTHS.					
January, 1870			November, 1870		
Cases.	Died.		Cases.	Died.	
2	1		2	0	
" 1871	2	1	" 1871	4	0
" 1872	1	1	" 1872	2	1
" 1873	2	1	" 1873	2	0
" 1874	3	3	" 1874	1	1
<hr/>			<hr/>		
10			11		
7			2		
Mortality per cent., 42 $\frac{6}{7}$.					

SUMMER MONTHS.					
May, 1870			June, 1870		
Cases.	Died.		Cases.	Died.	
3	1		3	1	
" 1871	5	1	" 1871	7	2
" 1872	1	0	" 1872	3	0
" 1873	1	1	" 1873	3	0
" 1874	2	0	" 1874	1	1
<hr/>			<hr/>		
12		3	17		4
<hr/>			<hr/>		
July, 1870			Aug., 1870		
" 1871	1	0	" 1871	3	1
" 1872	4	1	" 1872	4	0
" 1873	4	1	" 1873	3	0
" 1874	8	1	" 1874	3	1
<hr/>			<hr/>		
18		3	15		4
<hr/>			<hr/>		
Mortality per cent., 22 $\frac{6}{10}$.					

These figures apply, of course, only to certain years, but they are seemingly sufficient to reconcile statistics and principle until, at least, it is shown by actual demonstration that the apparent fallacy in the numerical argument does not exist. It is hardly possible that what is true of five years is not true of many years,—namely, that there is more business activity and consequently that there are more accidents in this region during the summer than during the winter.

A GOOD deal of interest has been excited by the report before one of the London societies of a case of injury in the spine, in which it is asserted that for a long time the temperature remained above 120° F., reaching even 125° F. It was noted at the same time that the feet were icy cold. The only record we have ever known equal to this was that of a Siberian traveller who stated that the weather was so cold that the birds froze stiff whilst flying, and that a mercurial thermometer registered —224° F. It seems to us most probable that there was some deception in the *Lancet* case; for the fact that the temperature was taken only in the ax-

illæ indicates that the gentlemen in charge did not so thoroughly appreciate the seeming impossibilities of their record as to guard against possible deception. There is much reason to believe that, in certain diseases, local rises of temperature occur, and H. Weber reports cases of hysteria in which the axillary temperatures as recorded were far above normal, although when the instrument was placed in the mouth the mercury failed to rise. How the deceptive rise was produced Dr. Weber could not determine; but all modern physiology teaches that a general temperature of 125° is simply impossible, and the record must be viewed as the result either of a deception or of an extreme localized fever.

PRE-EMINENT among all the private schools of medicine that have flourished on the Western continent, whether judged by the length of its life, the number of its graduates, or the fame of its teachers, is, and probably must forever remain, that school in Chant Street which has just been uprooted by the ruthless hand of the Government. Opened in March, 1820, its halls have been the nurseries of medical babes and the gymnasias of young medical athletes for more than half a century. Surely the memory of such an institution is worthy of embalming in that most abundant of all modern fluids,—printers' ink. It is, therefore, with great pleasure that we call attention to the farewell oration pronounced over the dying bed of the alma mater of such a numerous progeny.* Let every graduate furnish himself with this skilfully wrought monument, that now, if age be already come upon him, or in the future, if the evil days have not yet come nigh, he may, as a voyager upon a map, retrace the journeyings of his former years.

THE constant improvement in the opportunities offered in this city for the study of medicine during the spring and fall months is very great and very gratifying. To any one desirous of acquiring a thorough medical education, no city on the continent to-day holds out greater inducements. Indeed, we doubt if, on the whole, any other city is as well prepared to produce thoroughly educated physicians. Our clinical advantages are certainly superior to anything outside of New York, and now to them are added means of practical instruction upon the fundamental sciences of our art. Laboratories for histology and pathology, chemistry, and physiology are now being brought into operation, under most competent teachers.

* The History of the Philadelphia School of Anatomy, and its Relations to Medical Teaching. A lecture delivered March 1, 1875, at its dissolution, by William W. Keen, M.D. Philadelphia, J. B. Lippincott & Co., 1875.

CORRESPONDENCE.

NEW YORK MEDICO-LEGAL SOCIETY.

AT the regular meeting of the New York Medico-Legal Society, Thursday, March 25, Prof. F. H. Hamilton spoke on "Malpractice in Surgery; its Causes and Remedies."

He said he would take as a text of his remarks a letter which he had received a few days previously from a surgeon in Illinois, asking him if he had a form of agreement to be made between patient and surgeon, as without something of this kind it would not be safe, and it would be scarcely possible, to pursue the practice of surgery.

This was a fair specimen of the character of letters frequently received by him. Some of them anticipate the possibility of prosecution; others seek advice as to how they are to escape a threatened prosecution; and still others ask his counsel and attendance when they are actually prosecuted. It is patent to both the legal and medical professions that for the past few years in this country surgeons have been exceedingly subject to prosecutions. During that period extending from the year 1833 to 1866, prosecutions were so frequent in various parts of the United States, but he believed less so in the Southern States, that many eminent surgeons were obliged from self-protection to abandon the practice of surgery. He had known as many as four cases of prosecution for malpractice to occur in a single term of the court. Twenty-five or thirty years ago, there was scarcely a surgeon practising in the Northern States who had not been sued for malpractice, and one-half of whom had not been mulcted in damages.

Why is it that a special department in surgery is more liable to dangers than others? Why does it happen that amputations, and more especially fractures and dislocations, are more than any other branch of surgery exposed to prosecution? Is it because gentlemen who practise this department are less learned and less skilful than are those in other departments of surgery? He thought not.

During the last quarter of a century, foreign countries have not hesitated to give us the credit of superiority in the treatment of fractures. In their books on surgery, a large proportion of cases adduced is taken from this side of the water.

To what, then, shall it be attributed? He was disposed to attribute it to the fact that the profession itself has not ascertained fully what the science and art of surgery can accomplish. He had supposed, in his earlier days, that it was the lawyer—the mean, pettifogging lawyer—who spurred on cases of malpractice,—who induced unfortunate patients to prosecute in the hope that they might recover damages for personal injury. But he had long since changed his mind in this regard. He is now convinced that it is because the profession, while they have had a constant desire to elevate the science and practice of surgery, have not understood fully what is possible and what is impossible to be accomplished in the profession.

In every department of surgery save in the department of fractures and dislocations, surgeons have furnished themselves with statistics as to the relative degree of success of the various operations. It is indicated what percentage of recoveries and deaths to expect. But how is it with fractures and dislocations, which are the most frequent source of prosecutions?

He had constructed tables, the result of much and patient study, the first of which appeared in 1852, and they were published originally in the *Buffalo Medical Journal*. Up to the year 1859, this was the only serious attempt made to ascertain what is the average result in the treatment of broken limbs.

At the request of the American Medical Association, he had prepared a paper on the subject, in which he not only gave the cases as originally tabulated, but a large number of additional cases.

The speaker here referred to the labors of Mr. Pott, of England, who, by his work, succeeded in revolutionizing in that country the treatment of fractures and dislocations, by the introduction of the "physiological method." He employed an inclined plane. With various modifications, it had become the almost universal practice. Dupuytren and others in France did not accede to the views of Pott, so that the triumph was not so great as in England. In this country he gained but a very few followers. There was only a single advocate for his original method, while for the modification there were only two or three. At that time it was stated that the practice of surgery was a disgrace to English surgery; and now, at the expiration of many years, it is again stated, notwithstanding all the so-called improvements and advances, that the treatment of dislocations and fractures is a disgrace to English surgery. This statement at this time is attributed to an eminent surgeon in St. Bartholomew's Hospital,—Mr. Skey.

Now, the speaker was more leniently disposed towards the English surgeon than is Mr. Skey. He did not believe that the English surgeons are any less skilful in the treatment of fractures and dislocations than the French; neither did he consider them any less skilful than Americans. But they had failed to see what the real difficulty is, namely, *that there are impossibilities attempted and claimed which never can be accomplished!*

But Mr. Pott was not the only surgeon who thought that he had discovered a method which would be universal. Mr. South says that anything less than a nearly perfect limb makes the surgeon responsible. Others claim that a fractured thigh can be made the original length; while it is claimed by many that nearly all bones can be made to unite so that the original length can be preserved.

Now, these were the facts a few years ago. He would not say what had caused the change; but it has been frequently remarked to him by gentlemen of the legal profession that prosecutions for malpractice are not so frequent as they were a few years ago. It is evident that there was a decline up to a very recent period. They are, however, becoming more frequent, and the fact calls for an explanation. In the lapse of

time, as year after year rolls around, and he might say almost every year, and almost every month in the year, there are modifications in the treatment of fractures and dislocations. Almost invariably, when new modifications in the treatment of these accidents are announced, new prosecutions are instituted. This seems to have an unfavorable influence upon the people.

Now, in order to prevent this, it will be necessary that some one man shall stand up in every generation as a sacrifice; because whoever attempts to stand between surgery and prosecutions for malpractice must make an enormous personal sacrifice. He had sacrificed much for this purpose, and he proposed to revise his tables a second time. In his investigations so far he has discovered that there have been improvements in surgery, and that great advances have been made in the treatment of fractures, but only occasionally; a thousand things have been suggested, but it is only now and then that a single instance can be pointed out in which there is an advance. Perfection is still unattained. Surgeons still make a little shortening of one-half to three-fourths of an inch in fractures of the clavicle, and a corresponding shortening in fractures of the tibia and fibula.

The remedy for the legal trouble has already been indicated. It consists in not assuming in the treatment of fractures and dislocations more than surgery is able to accomplish. So long as more is claimed than can be accomplished, prosecutions will be instituted, and, he thought, justly. Surgeons cannot certainly complain if, having established a standard of perfection, and having failed to maintain it, the people resort to legal steps to obtain relief.

Dr. Hamilton concluded by calling upon Dr. Stephen Smith, who has been engaged for some years in collecting and collating material for an extensive work on surgical malpractice, to relate his experiences and add his remarks to those which had already been made.

Dr. Smith said he had devoted considerable attention to the subject discussed, and for the last twenty years has made it a business to collect cases with the view of finally publishing them in book form, in order to illustrate the legal responsibility pertaining to surgical, medical, obstetrical, and, lastly, dental practice. He believes that he has collected over two thousand cases. During the earlier history of mankind there was a period of unwritten medicine. At that period the practice of the art rested with patriarchs and priests. After a time, rules of practice were written. This was the beginning of written history. With this period began the history of suits for malpractice, for physicians were obliged to practise according to the rules laid down in the books, and they did not do it sometimes. If accidents happened under these circumstances, the surgeon was liable.

In later history, physicians were held to the latest improvements in the art; and at this day courts are laying down the rule that patients are entitled to the benefit of the best methods of treatment in vogue, and that every physician is in duty bound to know what are

the latest improvements, and to treat his patient skilfully. By the word "skilfully" the courts mean skill sufficient to cure the case, and practice according to the very best methods of to-day. And whether the physician or surgeon resides at New York or in Kansas, the courts will hold very much the same view. We are possessed of the means of such rapid diffusion of knowledge and information that the physician very remote from the centres of civilization and learning is as capable of acquainting himself with the latest improvements as his more centrally located brother. And the former cannot escape the responsibility of his actions any more than the latter. The courts have held and do hold them responsible, even according to the information diffused in the medical journals of the day. The physician and surgeon is expected to take the journals, and thus to keep up with the profession. The remedy, he thought, consisted in the publication of average results, and in not claiming too much. He thought that suits for malpractice in the end exerted a healthy influence, for they weeded out of the profession incompetent men, and made book-writers more careful in their statements.

Several lawyers spoke,—Messrs. J. F. Miller, D. S. Riddle, and others,—who thought the trouble rested with the doctors because they were all "at sea" with their facts, and unless they settled upon certain facts and confined themselves thereto they must expect trouble.

Dr. L. A. Sayre introduced a draft of a law which was originally drawn up by himself, and passed by the New York Legislature, but was vetoed by Gov. Hoffman, on the ground of special legislation. It was modified, and afterwards passed by the State of Ohio. He hoped this Society would lend its influence to its adoption by this State, and that it might be adopted by every State in the Union. Its purpose is to require plaintiffs in malpractice suits to give bonds for the expenses of the suit.

W.

REVIEWS AND BOOK NOTICES.

THE MAINTENANCE OF HEALTH. A Medical Work for Lay Readers. By J. MILNER FOTHERGILL, M.D.

Dr. Fothergill is very widely and favorably known to the profession on both sides of the Atlantic by his strictly professional writings, and an examination of the very handsome brochure before us convinces us that before long he will be as widely and favorably known among the more intelligent of the laity. Whilst there is little or nothing in the book absolutely new to the well-informed physician, yet almost any one can gather from its pages many suggestions for his own thoughts and many hints as to the management of patients; and all can conscientiously recommend it to their patients as containing a large amount of most important information conveyed in a most agreeable form. As an instance of the suggestiveness of the work, we mention one idea from its pages which strikes us as novel and plausible, but whose truth seems to us somewhat doubtful. The suggestion, which is conveyed in the most modest and commendable manner, is that in early marriage very frequently sexual indulgence is unbridled, and "that the eldest child in his recklessness and thoughtless self-indulgence tells of the life of the parents at the time of his genesis." We do not believe

that in this country the eldest child is as a rule any less self-contained than his younger brothers, and would rather be inclined to attribute the fact spoken of by Dr. Fothergill as existing in Great Britain to the law of entail. The knowledge that the property is inevitably to be his, the absence of business training, the peculiar deference paid by friends, the toadyism and indulgence of whims by servants, must have a tremendous influence upon the moral development of the eldest scion of a noble house.

LECTURES ON PATHOLOGICAL ANATOMY. By SAMUEL WILKS, M.D., F.R.S., and WALTER MOXON, M.D., F.R.C.S. 8vo, pp. 672. Second Edition. Philadelphia, Lindsay & Blakiston, 1875.

The first edition of this work was issued by Dr. Wilks in June, 1859, and consisted of a series of lectures which he delivered in a voluntary course during the summer session at Guy's Hospital, London. Based on a very large experience in a daily study of the dissection of the dead for fifteen years, and a personal record of between two thousand and three thousand cases, the book in its first edition was a valuable one, characterized by the correctness of its descriptions. Dr. Moxon has prepared the second edition, adding the results of a personal experience at Guy's Hospital, similar to that of Dr. Wilks, a sifting of the stores of facts contained in the invaluable "Transactions of the Pathological Society" of London, and an accurate knowledge of the modern pathology, as enunciated by Virchow and his collaborators. Through these means he has produced a volume which is a faithful and sufficiently copious exposition of morbid anatomy.

The order of arrangement pursued is that adopted in the museum of Guy's Hospital, and includes diseases of the bones; diseases of the joints; diseases of bursæ, tendons, and muscle; diseases of the heart; diseases of the arteries; diseases of the veins; diseases of the lymphatic vessels; diseases of the lymphatic glands; diseases of the nervous system; diseases of the skin; diseases of the respiratory system; diseases of the alimentary canal; diseases of the liver; diseases of the gall-bladder and ducts; diseases of the pancreas; diseases of the spleen; diseases of the supra-renal bodies; diseases of the urinary organs; diseases of the male sexual organs; diseases of the female sexual organs; and on the association of morbid conditions. It will thus be seen that the entire field of special pathology is covered; and it may further be said that there are few subjects which have not received a detailed consideration, while there are still fewer that are omitted; so that, by the aid of the copious index which is appended, the general practitioner can easily find some information upon any morbid specimen which may fall under his notice. For the wants, therefore, of the practitioner we know of no volume so well adapted. The close student of pathology will have to look elsewhere for those preliminary chapters on general pathology which are so necessary to a thorough knowledge of the subject. But his library will also be incomplete without this volume. It is mortifying to have to acknowledge that works on morbid anatomy have not generally a large sale in the American market; but the increased prominence recently given to the subject in some of our medical schools will tend to change this, and we hope the sale of this will be an exception to the rule. The typography, binding, and general appearance of the book are pleasing, and invite purchase. I. T.

CHLORAL AND IPECACUANHA IN CROUP.—In a bad case of croup with urgent dyspnoea, give to a child fifteen months old two minims of ipecacuanha wine, with two grains of chloral, every two, three, or four hours, according to the effect produced.—*Dr. G. Barclay.*

SELECTIONS.

NETTER ON THE POSSIBILITY OF CURING ACUTE PERITONITIS BY INJECTING A SUFFICIENT QUANTITY OF TEpid WATER INTO THE PERITONEAL CAVITY.—Dr. Netter (*Revue Médicale de l'Est*, January 15, 1875) quotes some remarks made by Kœberlé in 1867 on a case of his in which acute peritonitis threatening death occurred after ovariectomy, but was checked and the patient saved by incision into the right flank, where he detected dulness, and the escape of a quantity of red serum from the peritoneal cavity. He gives extracts from the speeches of Kœberlé, himself, and others, at a long debate which followed the reading of this case at the Strasbourg Medical Society. The cause of the speedy relief when the fluid is detected and let out at once in these cases was the chief ground of debate.

Kœberlé, while insisting on speedy action, attributed the danger to the fluid becoming rapidly septic from its contiguity to the intestines.

Netter objected to this—1. Because of the rareness of true idiopathic peritonitis (*i.e.*, excluding cases of perforation, etc.); 2, because of the rareness of this typhoid or septic form itself. He considered the first product of the inflammatory action as the most actively dangerous, and compared it to the acrid mucus which is discharged from the nostrils at the onset of coryza. He also pointed to the numerous successful ovariectomies of Kœberlé and others, successful in spite of handling of the parts, introduction of instruments, exposure to the air, etc., of the peritoneal cavity and its contents. These successes he attributed to the thorough cleansing of the peritoneum at the time of operation, and the speedy evacuation of any fluid which gathered afterwards.

The possibility of applying this principle to other forms of peritonitis was suggested by some of the speakers, and reflection on the subject led to the present proposal by M. Netter.

He considers it would not only be justifiable, but right, in cases of acute peritonitis, to make a small opening into the peritoneal cavity, and inject sufficient tepid water to dilute thoroughly its contents and form an artificial ascites. If relief follow, the injection should be repeated. He supports his proposal by the facts observed in the similar diseases of the pleuræ. When the pleura is dry the fever runs high, but when effusion comes the symptoms abate; and when effusion occurs at the onset often there are hardly any symptoms. Even when some fluid is effused into the peritoneum it gravitates, and the intestinal and upper surfaces become glued with the lymph. He affirms—1, that the liquid secreted in acute peritonitis has only noxious properties in proportion to its concentration; 2, that, largely diluted with water, it loses these noxious properties.

He gives in full an old paper by Dr. Herlin in 1767, on some experiments which he and others made on cats and dogs, ligaturing the bile-duct and puncturing the gall-bladder, and letting the bile into the peritoneum, afterwards practising warm-water injections. The animals appeared none the worse for the operation, though dogs, as Netter points out, are specially liable to peritonitis. He arrives at the following conclusions:

1. It is possible to cut short acute peritonitis by injections at its commencement.

2. If Herlin's experiments be repeated without the injections and the animals die, it will be because the injections were not used.

3. Since it has become a recognized practice to use injections when peritonitis comes on after ovariectomy, etc., so it should be in the other forms of peritonitis where there is no surgical opening to begin with. He

considers the adhesions formed by the intestines in puerperal and other cases a cause of the extreme gaseous distention and consequent dyspnœa and collapse: if the injections alone will not separate these adhesions, aid may be given by simple punctures, to let out the gas. He quotes from Kœberlé that these adhesions lead to little pouches full of serum or pus. In a note at the end of the paper he advocates leaving the wound open after herniotomy, and injecting, if necessary.

[The reporter has several times noticed the pouches referred to in post-mortem examinations, and that they are surrounded by extra inflammatory action: mere puncture and draining of course give no exit for such collections of serum or pus.—*Rep.*]—*J. Knowsley Thornton, in London Medical Record.*

LORAIN ON CASES OF SUDDEN EMOTIONS IN WOMEN PRODUCING PERSISTENT NEUROSES, SUCH AS HYSTERIA, CHLOROSIS, CHOREA, AND PARALYSIS AGITANS.—M. Lorain, after noticing the popular tendency to argue on the *post hoc ergo propter hoc* principle in nearly every disease, asserts that this tendency has caused medical men in many cases to treat such accounts with skepticism. "We have good reason," he says, "to reject these two facile explanations; but should we therefore always refuse them in a spirit of routine, or should we sometimes admit them, and to what extent?"

With a view to the settlement of these questions, he submits to notice the following reflections on cases which have occurred in his own experience. In each of these cases there has been some sudden emotion followed by neuroses, which have persisted for a greater or less period.

Other considerations arise from the study of these cases. Among these are the following: Does the accident decide the seat of the morbid manifestations which follow it? Have such accidents corresponding morbid conditions? Is it right to call a woman hysterical who suffers from hemiplegia, or who falls into a state of clonic convulsions with globus hystericus and other morbid sensations?

Shall a woman, however, who becomes after a similar accident choreic, be excluded from the ranks of hysterical patients because of her chorea?

Is it also necessary to make a separate class for chlorotic patients?

The author protests against such exclusiveness, and proposes that all the cases of neuroses occurring in women after sudden accidents should be included in one term, *Féminisme*.

Among the observations recorded are the following. Two girls suffered from chorea following fright. At the time of the accident they were menstruating, and in consequence of it the discharge was immediately arrested. In one the chorea is combined with rheumatic symptoms; in the other there are so many undoubted hysterical symptoms that she must be classed among the hysterical patients. [Is it not probable that the latter of these two patients has imitated the choreic symptoms of the former? They are reported to have been in the same ward.]

In another case, a girl, aged fifteen, who had been ailing and out of sorts for some time, was startled during menstruation by a flash of lightning, which struck the ground about thirty yards from her. The catamenia were arrested, after having lasted for but a small portion of the time they generally did. The next day she was attacked with chorea, which became very severe.

Another girl, aged twenty, after the bite of a horse, was seized with hysterical convulsions, which were followed by loss of cuticular sensibility, and ataxic symptoms. In another case of a girl, aged twenty, after the receipt of some bad news, hysterical paralysis occurred.

The last case related is that of a girl, aged seventeen, who was attacked by paralysis agitans after having been frightened during the siege of Paris by the explosion of a shell which killed several people who were standing near her.—*W. Kesteven, Jr., in London Medical Record.*

THE COUCHARD.—Dr. Diver, of Caterham, has invented a very ingenious contrivance for exerting pressure on the abdomen and back of parturient women, which he styles the "couchard." It is a kind of apparatus which the woman puts on during labor, and the patient is enabled, by pulling during the pains, to give considerable pressure to the back and support to the uterus at the same time. The patient puts on a pair of connected pads, one over the back, the other over the front of the body, and then places her feet in a pair of stirrups. Through the tops of these stirrups a cord running from the handle passes so that the hands and feet act in antagonism. This tightens the cord, which is attached to a soft cushioned pad over the back, which draws that pad and the one in front together, and gives great relief to the patient.

Patients have expressed themselves as greatly pleased by the support this very ingeniously devised apparatus affords to them during labor. Dr. E. Diver has taken much trouble in perfecting this invention of his, and writes us that additional experience shows him how much relief it gives to many of his patients. We should mention that, by means of a strong cord attached to the handle, and pulling over the end of the bed, the patient can employ the same abdominal and back pressure comfortably whilst lying in bed. All such devices for assisting in the alleviation of suffering are highly commendable, and we wish success to Dr. Diver's Couchard.—*Medical Press and Circular.*

DUBOUX ON RHEUMATISMAL INSANITY.—In a case of rheumatismal insanity reported in the *Bulletin Médical de la Suisse Romande* for December, 1874, the patient was suffering from acute articular rheumatism with endocarditis, and presented all the characteristics of rheumatismal madness,—combination and alternations of various forms of mental alienation, mania, melancholia, dementia, with a marked predominance of notions of persecution and hallucinations of sight and hearing of a generally distressing character. For several days there was marked stammering, a symptom which has before been noted in some cases of this kind. M. Duboux brings into notice the commonness of melancholic mania in rheumatismal insanity; in the great majority of cases coinciding with cardiac disease. On the other hand, it is interesting to note how among lunatics suffering from the persecution-delirium, generally with persistent hallucination, we find individuals laboring under heart-disease, especially among old men.—*London Medical Record.*

GLEANINGS FROM OUR EXCHANGES.

EXPLORATION OF THE ABDOMINAL CAVITY IN EXTREME CASES OF OBSTRUCTION OF THE BOWEL.—Mr. Teale (*Lancet*, March 13) believes that if further experience should strengthen the growing surgical opinion in favor of greater boldness in opening the peritoneal cavity, we may look for as great an advance in the management of many obscure and hitherto hopeless cases of obstruction of the bowel as has taken place in the once deemed hopeless cases of ovarian disease.

As a contribution to the knowledge of this subject, Mr. T. gives notes of the following case:

He was consulted in October, 1873, by a man forty

years of age, for severe pain in the small of the back, distressing when he moved about, most severe at night. He passed blood and mucus from the bowel, and the evacuations were small and narrow. On examination, nothing was found amiss with the rectum. He was advised rest, with occasional morphia suppositories, and careful regulation of his diet. Under this treatment the evacuations became perfectly regular and natural, except that the discharge of blood and the pain did not cease.

Five weeks later, a small tumor was felt near the left iliac fossa. He was then ordered to take small doses of Dover's powder, and to make further modifications of diet, the result of which was that the discharge of blood gradually diminished, and since Christmas, 1873, has not reappeared. At Christmas he resumed work, though suffering at times as much as ever from the pain in the back. From Christmas to June he got on fairly well, easing his pain by suppositories and Dover's powders, and having a *solid, fully-formed evacuation* daily, free from blood and mucus.

In the middle of June the action of the bowels, which up to this date had continued to be perfectly natural, was suddenly arrested; aperients and enemata were of no avail, and the body became intensely tympanitic. At the end of ten days, during which no relief could be obtained, by the advice of his medical attendant, Mr. Atkinson, he was admitted under my care, at the Leeds Infirmary, on July 1, 1874.

After his admission, he was treated by nutritive enemata and hypodermic injections, with a very small allowance of brandy and milk by the stomach.

At the end of four weeks from the commencement of the complete obstruction, all hope of spontaneous resolution was abandoned. During the latter three or four days he had suffered excruciating pain, had lost flesh rapidly, and had several times been delirious; and it seemed as if, unrelieved, he could not possibly live more than three or four days.

After consultation, it was decided to open the abdominal cavity in order to search for the seat and the cause of the stricture, and to determine the possibility of relieving the obstruction by right or left lumbar colotomy.

The patient having been chloroformed, an incision was made in the middle line below the umbilicus, and manual exploration made. The first points made out were the distended cæcum and the junction of the ileum with the colon. The ascending colon and the transverse colon were then traced, which latter, owing to its extreme distention, first descended to the pelvis and then doubled back and ascended in front of the left lumbar region to the left kidney, lying in front of and concealing the descending colon. Finally, below the crest of the ileum the distended bowel was felt to terminate in a hard mass of the size of a walnut, apparently attached to the bowel, and puckering it. It was clear, therefore, that left lumbar colotomy would give the relief desired. Five wire sutures were then introduced into the wound and tightened temporarily as far as was deemed prudent, considering the tense state of the abdomen. The patient having been turned to a prone position, the usual operation of Amussat was performed in the left loin. The opening of the colon was followed by a large escape of flatus and of semi-fluid fecal matter, which so far reduced the distention of the abdomen as to allow the wire sutures to be tightened up, and effectually to close the wound in the front of the abdomen.

The patient made a good recovery from the operation. For the first day or two large quantities of liquid fecal matter escaped by the lumbar opening, and about the third day some solid scybalous matter was evacuated per anum, the passage of which was attended with

very severe pain. By degrees more and more of the contents of the bowel escaped per anum, until, at the end of three months, not more than one-fifth passed through the lumbar opening.

Three months later, and six months after the operation, he was feeling better than he had for a year past. It was feared, however, that the disease might be returning, since there was a good deal of pain and bearing down, and but a small portion of the fæces were passed per anum.

Mr. Teale adds two cases of somewhat similar operation in cases where peritonitis had set in, the result being in each case, possibly from too long delay, unfavorable.

REMARKABLE ELEVATION OF TEMPERATURE.—At a recent meeting of the Clinical Society (*Lancet*, March 6) Mr. J. W. Teale read notes of a case occurring under his care, of which the following is an abstract:

A young lady, thrown from her horse in the hunting-field at the beginning of September, 1874, sustained fracture of two of her ribs and some obscure injury to the spine. In due course the fractured bones united, and all would have gone well but that the pain and tenderness in the back ominously persisted. Symptoms of spinal meningitis set in, and, concurrently with them, the temperature of the body, which had regained the normal shortly after the accident, began to rise. One month after the accident it was 101° , in another month it reached 105° , and thence its extraordinary and unprecedented progress can only be reckoned by days. Between November 8 and 12 it fluctuated between 110° and the great elevation of 118° . But it did not stop here. The next day it on two occasions reached 122° , falling in the interval to 114° . Thence the rise and fall of the index of the thermometer was strange in the extreme, and it would be tedious to refer here to all its fluctuations. Suffice it to say that it kept for three weeks between a minimum of 108° (on one occasion only) and a maximum of 122° ; throughout December it registered the comparatively low level of 110° during the first half of the month, mounting up to between 112° and 114° during the second half; and then, in the early days of January, it rapidly subsided to 104° , becoming normal on the 10th of the month. The condition of the patient during this very super-normal state of body heat was, save in the periods of highest range, apparently not one of extreme danger; we gather, indeed, that during December her general health was improving and the spinal symptoms were slowly but surely subsiding. Nor were the circulatory or respiratory functions much deranged, the pulse never being above 120, and the respiration not being notably embarrassed. To be sure, she emaciated much and was extremely prostrate, the catamenia ceased, and the urine was very scanty and loaded; but a continuous body heat of 102° or less, lasting for two months, would *a priori* have done as much.

The utmost care was exercised by Mr. Teale in order to remove all sources of error. No fewer than seven thermometers were used in the course of the case; they were inspected by two or three trustworthy witnesses before and after each application, and the results were always immediately recorded in writing. The temperature was taken in the axillæ by two thermometers at once, and then these were interchanged and the observation repeated.

APOMORPHIA.—Within the last two years much has been learned of this drug, which seems likely to prove a valuable addition to therapeutics, and recently a tolerably complete monograph upon it has been published by M. Victor Bourgeois (*De l'Apomorphin; Recherches cliniques sur un nouvel emetique*, Paris, 1874).

The conclusions to which this author is led (*Dublin Med. Jour.*, March) accord in all essential points with

the observations of Marthiessen and Wright, and are briefly as follows:

1. Apomorphia, or rather hydrochlorate of apomorphia, when pure and employed in suitable doses, is a rapid, simple, and harmless emetic.

2. It is *rapid*, for its action always takes place at least within ten minutes after administration.

3. It is a *simple* emetic, for it does not appear to exert any influence upon the other functions.

4. It is innocent, and does not seem to possess dangerous toxic properties.

5. Lastly, the facility with which it can be administered by hypodermic injection fulfils a therapeutic desideratum, and suggests its adoption by physicians in some special circumstances, such as the medication of children and of the insane.

As an average dose, for an adult man, of the Scotch hydrochlorate of apomorphia prepared by Macfarlan & Co., Edinburgh, M. Bourgeois fixes on one-sixth grain hypodermically and one-half grain by the mouth. The best form of solution is that obtained by dissolving one part of the salt in one hundred parts of distilled water. If the proportion of the salt be greater the solution becomes muddy, and it is necessary to add one or two drops of HCl in order to clear it,—a serious objection in the case of a liquid intended for subcutaneous injection.

TWO CASES OF IDIOPATHIC TETANUS—TREATMENT BY CHLORAL—RECOVERY.—The *Indian Medical Gazette*, February 1, contains the following cases:

The first, a boy 13 years of age, was treated by Surgeon-Major G. T. Hunter for tetanus, occurring after exposure to the sun and beating with a cane. No contusions or wounds could be discovered. Two peculiarities were noticeable: 1. The tetanic spasm commenced at the diaphragm, then affected the fingers of the right hand, and afterwards extended to the muscles of the abdomen and legs. 2. Deglutition as regards liquid nourishment was easy throughout the course of the disease, though he could not open his mouth more than half an inch for several days. Treatment: tr. cannabis indicæ, ℥ x, and potass. bromid., grs. v every third hour, and chloral hydrat. grs. xii three times a day, together with inhalations of chloroform as required. The diet was generous, and the boy took as much as twenty-two ounces of wine daily, without any intoxicating effect. Recovery took place in about a month.

The second case, under care of Surgeon H. W. Hill, was that of a Hindoo, 40 years of age, who suffered from a severe but typical attack of idiopathic tetanus, caused probably by exposure to the damp chilly air of night, when the body was relaxed by the heat of the day and the constitution rendered "below par" by a recent febrile attack.

During the first few days the tetanic spasms were exceedingly frequent and severe, but these gradually yielded to the steady administration of chloral hydrate, grs. xx thrice daily, which was kept up through the whole course of the disease, which terminated in recovery at the end of six weeks.

TWO CASES OF TETANUS FOLLOWING FROST-BITE.—The following cases are recorded in full in the *Canada Lancet*, March, 1875. They occurred under the care of Dr. Bethune, of Toronto. The first was that of a farmer who was exposed to intense cold for about three hours while driving. His feet and fingers became severely frost-bitten without his becoming aware of the fact until he arrived home. On admission to the Toronto General Hospital, four days later, the toes and the greater part of both feet were found in a condition of moist gangrene.

The fingers and parts of both hands on the dorsal surface were black and dry. Four days after admission

he was seized with tetanic symptoms, which rapidly developed. Chloral hydrate in thirty-grain doses, with extract of calabar bean in one-fourth-grain hypodermic doses until five grains had been given, failed to combat the disease, and the patient died in thirty hours after the accession of the attack.

The second case was that of a man who, having lain out in a barn all night, had both feet severely frost-bitten, subsequently becoming partially gangrenous. In this case trismus set in nine days after exposure, and soon developed into well-marked tetanus, to which the patient succumbed in about thirty hours.

The treatment in this case consisted in hypodermic injections of, first, one grain of morphia, and subsequently the same in one-half grain injections every hour.

EXTIRPATION OF THE PAROTID GLAND FOR MALIGNANT DISEASE.—Dr. Charles Brigham communicates to the *Western Lancet* for February, 1875, the notes of a case in which he had removed the entire right parotid successfully by means of a curved vertical incision two and a half inches in length, with the concavity towards the lobe of the ear, with subsequent dissection by the aid of both scalpel and fingers. Eight ligatures were placed upon arteries, the wound cauterized with pure carbolic acid, and dressed with cotton-wool and Lister's gauze.

The tumor weighed two ounces, and was of cartilaginous hardness. Under the microscope it was found to contain small oval cells. The patient recovered without an untoward symptom. The facial nerve having been severed in the course of the operation, partial paralysis of the parts supplied by it was the result. Six weeks later the paralysis of the face was better, but the upper eyelid was still paralyzed, and there was little if any hearing in the ear of the affected side.

MISCELLANY.

ON BAPTISM AT BIRTH.—In every community composed of religious bodies holding different tenets of faith on some points, it is believed to be conducive to harmony and good feeling, as well as consistent with that broad and liberal catholicity of sentiment that should always characterize the professor of the healing art, to conform to the usages of his patrons respecting rites having, in their views, important religious significance.

As containing an authorized expression of the views of the Roman Catholic church respecting baptism, the following translation from the "*Cours d'Accouchements*," a recent great work on obstetrics by Dr. L. J. Hubert, Obstetric Professor in the Catholic University of Louvain, is submitted to professional readers:

This work is especially dedicated to the young gentlemen who come to this Catholic University to receive their medical education. Believing that it may be useful to those who may be frequently called to administer this sacrament to draw their attention to the teaching of the church, I have decided to finish this "*Cours d'Accouchements*" by a special chapter on the subject of ante-natal baptism of infants.

When an infant is not in immediate danger of death, it is at the church and by a priest it should be baptized; but when its life is imperilled, baptism may be conferred everywhere and by everybody (ecclesiastic or laic, man

or woman, believer or infidel), and it is valid, provided it is administered with the *intention*, the *material*, and with the *formula* required.

Who, in case of peril, should administer baptism?

If the child is born, and a priest is present, he should always perform the rite. The father or mother may perform it only in the absence of any other qualified person. If the infant is born, and there is a man present capable of performing it, he should do it in preference to any woman, or even a midwife. If the foetus is not born, baptism in utero should be administered, either by the obstetrician or midwife in attendance.

The general purpose or intention to do what the church does is sufficient.

The material is water, pure water, from spring, river, or well, and whether previously blessed or not.

The formula is: I baptize you in the name of the Father, of the Son, and of the Holy Spirit.

This formula should be distinctly articulated, and loud enough to be audible to the person himself.

The baptism is absolute or conditional according to circumstances, as we shall proceed to show. The manner varies as to whether the child is born or not.

A. If the child is born, the baptizer should himself pour water on the head of the child at three times, corresponding with the mention of the respective names of the Holy Trinity.

If there is any doubt respecting the life of the newborn, the formula should be modified thus: If thou art living, I baptize thee, etc.

If there exists any doubt of the human nature of the being to be baptized (viz., if a marked monstrosity or rudimentary embryo), it should be added, "If you are a rational being, I baptize you," etc. Abortions should receive the rite in the same manner and modified in the same manner as the infant at term.

If the ovum should be expelled entire, the baptism should first be done through the membranes, saying: If you are fit to receive baptism, I baptize you, etc.; then, having opened the membranes, the rite is repeated, adding, if thou hast not been baptized. When the baptism is thus conditional, the condition mentioned must be distinctly articulated; it is not sufficient merely to think or to will it. Such is the canonical law.

B. Supposing the foetus is still in whole or in part unborn, it then becomes necessary to baptize it in utero, varying the method according to circumstances.

(a.) If the head is delivered, it may be baptized, either absolutely or conditionally, as if the birth were completed, and no subsequent baptism will be required.

(b.) But if an arm or foot present, those parts should be baptized, and the danger persisting, the chest and the head should be successively baptized, with the formula: If thou hast not been baptized, etc.

(c.) But if the foetus is still enclosed in the uterus, the baptism should be performed by carrying the fingers, or a piece of lint or sponge, or using a siphon or syringe, and with the formula as before stated, and modified according to the circumstances. After birth it may be rebaptized if alive.—*Peninsular Journal of Medicine.*

THE DAWN OF LIFE.—Professor Williamson, in a lecture on the "Dawn of Life," delivered at Glasgow on the 2d ult., referred to the experiments of Dr. Bastian, and remarked that one positive experiment showing that animal life did not result after the application of heat and the careful exclusion of the atmosphere was of more value than a hundred experiments giving an opposite result. He mentioned an interesting fact derived from the recent experiments of two Liverpool gentlemen who had sedulously watched by a powerful microscope the habits of the infusoria. They subjected the water in which they were contained to 250° of heat, and found that, while the mature animalcules were destroyed, the germs were not, but a heat of 300° destroyed the germs also. Professor Williamson believed that if these experiments were verified, the question of spontaneous generation might be considered to be practically settled. The deepest reaches of the microscope had shown that life was produced from life,—that this one universal law prevailed in the organic world, just as the farthest reaches of the telescope had shown that gravitation prevailed in the remotest systems in space.—*London Medical Record.*

At the last meeting of the Board of Trustees of the University of Pennsylvania, Dr. James Tyson was elected Professor of Pathology, Dr. Louis A. Duhring Professor of Diseases of the Skin, and Dr. H. C. Wood Professor of Diseases of the Nervous System, in the University Hospital.

"PUNCH" ON HOLLOWAY'S ASYLUM.—*Punch* furnishes this inscription for the front of the idiot-asylum founded by Mr. Holloway, who made his fortune in "patent medicines":

"Not oft is fate so just: see wealth restored
Back to the simple source from which it poured."

NOTES AND QUERIES.

A STATED meeting of the Northern Medical Association of Philadelphia will be held at their hall, 608 Fairmount Avenue, on Friday evening, April 23, at 8 o'clock.

Dr. A. K. Minich will read a paper on "Purpura Hæmorrhagica treated by Ergotin."

The medical profession are cordially invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM APRIL 6, 1875, TO APRIL 12, 1875, INCLUSIVE.

ROSE, GEO. S., ASSISTANT-SURGEON.—Assigned to temporary duty at Madison Barracks, New York. S. O. 69, Military Division of the Atlantic, April 10, 1875.

ELBREV, F. W., ASSISTANT-SURGEON.—To report to the Commanding General, Department of the South, for assignment to duty. S. O. 63, A. G. O., April 10, 1875.

CHERBONNIER, A. V., MEDICAL STOREKEEPER.—Granted leave of absence for one month. S. O. 63, c. s., A. G. O.

ERRATUM.

For Dr. Gebhard, read Dr. Gerhard, in the report of the County Medical Society Meeting in our last issue.

SATURDAY, APRIL 24, 1875.

ORIGINAL COMMUNICATIONS.

TYPHOID FEVER: ITS DIAGNOSIS, PROGNOSIS, AND GENERAL MANAGEMENT.

BY J. G. HAMILTON, M.D.

MR. PRESIDENT and Gentlemen of the Society: By invitation of your Business Committee it has become my duty to prepare a paper for this evening; and as in the past season typhoid fever, in relation to its causation and extension, was introduced to your notice, so, on the present occasion, some cursory remarks will be offered in reference to its diagnosis, prognosis, and general management.

There is not the charm of novelty in the subject now a second time presented for your discussion; it is, in fact, many years since a most intelligent member of your then Business Committee objected to an evening being spent in the consideration of typhoid fever,—so trite was the subject then regarded. But the disease, like phthisis, is to be met with almost everywhere, and prevails frequently in an epidemic and fatal form, exhibiting, in its career, singularly interesting and exceptional symptoms in connection with equally exceptional post-mortem conditions. The opinion, moreover, gaining ground that the disease is very often of local origin and susceptible of prevention, it has for some years past, like phthisis, claimed and received from gentlemen occupying the front rank in our profession renewed and earnest attention. The subject, too, is altogether a practical one, and as nearly all present must have had cases under treatment you have become more or less familiar with the march, terminations, and, probably, post-mortem appearances of typhoid fever, and are thus qualified to contribute some fact, observation, or deduction illustrating the topic before us. The discussions that follow the introductory papers read here should, as a rule, be the more important object of our assembling in this place, and if, in these “discussional meetings,” as they are called, subjects merely novel, or having no general practical application, are too often introduced, the interest flags; for in such cases either no discussion ensues, or it is too limited in extent or superficial in character to embrace much that is advantageous in practice. The diagnosis, prognosis, and general management of typhoid fever are the points, then, to which your attention will for a short time be called; not in a formal attempt on my part, in a paper of this length, to examine in detail or to determine that which may be true, or false, or doubtful in this connection, but rather in presenting some cursory observations bearing upon each point designated, that may serve to elicit from members the facts and observations within their experience, and the deductions or conclusions to which their practice, reading, and reflection may have given birth.

The late Professor John K. Mitchell once re-
VOL. V.—30

marked to me that he had often found, in consultation with physicians of considerable experience, that the diagnosis of typhoid fever, especially when insidious and in its first stage, caused them a good deal of embarrassment. The trouble then, as at the present time, was to distinguish it from typhus fever, bilious remittent, at that time very prevalent, local subacute inflammations, and a general typhoid condition often met with in various affections. In this city, or the adjacent country, there need not be much difficulty in assigning to its proper nosological position a well-marked case of typhoid fever, as distinct from typhus. Without occupying time by a general detail of the divergences observed in the symptoms of these two fevers, it may here be stated that the earlier period of the eruption in typhus, its much greater extension over the surface of the body, with its strongly-marked measly character, will, in general, serve, even in the early stage, to distinguish it from typhoid fever. Independent of the earlier and less positive diagnostic symptoms, there are collateral circumstances that possess no mean value where doubt exists. Typhus is found most frequently in the vicinity of wharves occupied with foreign shipping, and in almshouses, jails, or similar public institutions. If isolated cases are occasionally seen remote from such points, they can often be traced back to these sources. Typhoid fever, on the contrary, makes its appearance, and spreads, often with great fatality, in inland sections of the country. The liability, moreover, to either malady in reference to age, is another element that must not be overlooked, the great susceptibility of youth and early manhood to attacks of typhoid presenting a striking contrast to what is observed in typhus fever. Another fact of importance in this connection is the extreme disparity in the frequency of occurrence of these two fevers. Of fifty cases of continued fever to which the physician in private practice in this vicinity might be called, probably forty-five, at least, would prove to be typhoid, nor would it be surprising if, under the conditions in view, he should not meet, in one or more years, a case of typhus fever. Bilious remittent fever, to a great degree supplanted by typhoid, still occurs frequently upon the low grounds skirting cities and in similar places in the interior, and, despite the term remittent, occasions, at times, in reference to typhoid, more difficulty in the diagnosis than does the latter in regard to typhus. The remissions in bilious are sometimes no more conspicuous than in typhoid fever, and when the latter is accompanied with biliary derangement, constituting the bilious typhoid of Chomel, the diagnosis may be perplexing, unless the thermometric indication should be of unequivocal character.

The more important difficulty in the diagnosis of typhoid fever is in relation to certain conditions simulating those observed in this disease, and thought to arise from persistent irritation of certain organs, or nervous centres,—or from subacute inflammation of the same; or, again, in the general typhoid state so often met with in practice, the product, perhaps, of the local affections just alluded to,

or the result of some obscure general physiological abnormalities of which we are profoundly ignorant. The most frequent and deceptive of the local affections are those of the brain, spinal marrow, respiratory organs, and intestines. That deaths from these affections, especially when accompanied with the general typhoid state alluded to, are often returned to the Health Office as typhoid fever, cannot be doubted, whilst typhoid fever may be so strongly complicated with local disease as to embarrass even the experienced practitioner, and be returned under the name of one or another of the complications designated. Errors of this kind cannot well occur, unless in the exceptional cases alluded to; for where the disease is fully developed, and presents its prominent features, as seen in the headache of the first week, the characteristic diarrhoea, the eruption, distinctive in form and time of appearance, the epistaxis, the tympanitis and gurgling in the right iliac region, the hemorrhage from the bowels, and, possibly, in addition, symptoms indicative of perforation, there can be no doubt as to the nature of the malady. Comparatively few cases, however, exhibit the combination of symptoms here cited, and in the early period of the disease some of them are not to be seen, or may be absent altogether, and yet a fatal issue ensue. The physician should endeavor to determine, if possible at an early period, the nature of the attack, for this is the time when the patient and friends are anxious to know its real character.

The prognosis, as in other cases, must be based upon a just consideration of what experience has shown to be the favorable or unfavorable symptoms and signs of the disease, taken in connection with the all-important collateral agencies of situation and surroundings, in regard to ventilation, cleanliness, nursing, and appropriate alimentation. A guarded general prognosis is, in an especial manner, all that can be attempted in this disease, so various in its complications and uncertain in its mode of termination, especially in reference to that fearful accident,—perforation,—never in our power to predict either from the earlier or the actual symptoms. The duration of typhoid fever, omitting exceptional cases, is, as you are aware, in general terms, from one to six weeks. When, as it sometimes happens, a single week limits the march of the disease, death is nearly always the result, from passive congestion of organs essential to life; and such cases may occur as well in the young and robust as in the aged or broken-down. When the attack begins or is soon followed with violent and persistent delirium, it is liable to prove dangerous or fatal at an early period. If delirium, active or passive, having ceased for a week or more, should again return, the prospect of recovery is much diminished. Greater or less activity of the pulse and fever does not, within certain limits, of itself furnish any decided indication of danger; neither does the singular and sudden fall in the frequency of the pulse, sometimes observed, portend an unfavorable issue. If the patient rest heavily upon his back with limbs extended, and breathe laboriously and with unusual noise, the danger is imminent; and if to this condition irreg-

ularity in respiration supervene, the case may be deemed wellnigh hopeless, as in all probability serious brain-complication has taken place. A very red, smooth, glazed or chapped surface of the tongue, or when covered with dark sordes, denotes, undoubtedly, a severe attack, but indicates in no decided manner actual and extreme danger; yet a livid tongue, or when it is very tremulous and unnaturally pale, though otherwise moist and natural, is more significant, and implies danger from congestion. The disappearance from the tongue of tremor and difficulty in exposing it when requested, is a most encouraging change, and not less cheering are increased quickness in the motions of the eyes and greater power of deglutition. Moderate diarrhoea, with slight tympanitis, may be expected, and only when excessive can danger be apprehended from this condition. In this connection it may be stated that Dr. Nathan Smith "never saw a fatal case of typhoid fever where diarrhoea was absent." Hemorrhage from the bowels, if moderate and seldom repeated, cannot generally be regarded as very dangerous, yet will naturally cause anxiety, from our inability to foresee the moment and amount of a possibly impending hemorrhage. Alarming as a discharge of blood from the bowels, even in small quantity, is regarded by the patient or friends, it has often proven critical and salutary, by an immediate and permanent improvement in the general condition; and hence the question arises whether the practitioner of the present day is not too timid in reference to using the lancet. When a patient, seriously unwell of the disease, expresses himself as being nearly or quite well, proposing, perhaps, to dress and go to business the same or the ensuing day, the physician will generally be safe in pre-saging a fatal issue, though the event may be still distant. In conversation with the late Dr. J. K. Mitchell, in regard to this delusion, he said, "It is evidence of an utterly subverted and broken condition of the whole nervous system."

Dr. Austin Flint regards the robust and fleshy as more likely to succumb to the disease than persons of a moderate conformation,—a view coincident with that of many other practitioners. By the same eminent authority the belief is expressed that typhoid fever does not often prove fatal independent of local complications,—an opinion that we think must be accepted with some hesitation. Bilious fever, formerly so prevalent, whilst comparatively free from local complications, ended very often in death; the typhoid form of fever, from its greater tendency to prostration of vital force, should, even when uncomplicated, yet strongly developed, as in an epidemic season, prove at least equally destructive to life. Attacks of typhoid fever after merely a short abode in places where the disease exists were thought by Chomel to be more fatal than after a more protracted residence in such places, and with this view the observations of Louis and others coincide. Statistics prove that the mortality of the disease increases with age, yet they also demonstrate that the deaths are greatly more frequent in young persons, the malady not prevailing to a great extent among very young children or the

aged. From puberty until the twenty-first year is a very fatal period for the disease, arising, perhaps, from this being the season of rapid growth and constitutional change. When treating the complaint, it should be borne in mind that recoveries are frequent under a combination of circumstances apparently of the most adverse character, so that a premature fatal prognosis should be guarded against by the medical attendant.

In entering upon the general remedial and medical treatment of typhoid fever, we are to bear in mind two circumstances: first, that the disease, unless hastened through its march by the occurrence of fatal passive congestion or active inflammatory complication, is of long duration, rarely reaching its critical stage before the lapse of from three to four and a half weeks, a large proportion of the deaths occurring within these limits, or symptoms of improvement then taking place. The other circumstance is that this disease is apt to occasion unusual alarm to the patient and friends,—much more, perhaps, than is warrantable, were it not that the knowledge is pretty widely diffused that, with the most promising symptoms, fatal perforation may, in the latter stage of the disease, or even when convalescence is apparently far advanced, suddenly blast the flattering prospect in view. It is, in part, the apprehension of this possible catastrophe that continues so long to cause anxiety, and leads, perhaps, to a more protracted attendance upon the part of the physician than occurs in any other acute disease. These two conditions, then, in connection with others of similar character, will serve to show how important it is that we lose not sight of the psychological features of the case, capable of determining, as they sometimes are, in favor of life or death, so nearly balanced in this disease may be the struggling agencies tending to one or the other issue.

It is all-important that the patient occupy, if possible, a room of sufficient size, that admits of perfect ventilation, yet without exposing him to currents of cold or damp air, as this would augment the risk of a bronchial affection that very often complicates the disease, and may finally terminate in phthisis if there be a predisposition in this direction. Instruction should therefore be given regarding the location of the bed; and it is best generally not to have either side to the wall, so that the patient may enjoy more freedom and convenience in changing his position,—an object important in more than one respect. Light should be admitted, when there is a choice, from the proper direction, and in greater or less amount, having due regard to the wishes of the patient and the exigencies of the case. Encumbering the chamber with bed- or body-clothing, or other woollen or cotton material not in use, should be prohibited, and every unsightly or other object that might arrest the attention and annoy the patient, either in his calm or delirious moments, should be kept from view. In a disease so protracted it is of great importance to keep the bed in perfect order, permitting no portions of this or of the body-clothing to gather into welts or folds, especially when the patient, half delirious or semi-conscious,

with diminished sensibility, is in no condition to call attention to that which may result in excoriations or ulcerations of serious character, so serious, perhaps, as to turn unfavorably the balance now wavering between life and death. Strict attention is to be given to cleanliness, the timely change of clothing, and the immediate removal of offensive excretions. If the patient is unable, the nurse should make it her duty to cleanse his mouth, gums, and teeth with cool water occasionally,—the patient generally receiving this as a grateful and refreshing operation. The hands and wrists, the feet and legs, should often be bathed, and gently chafed with a morsel of woollen material wrung from warm whisky and water, so that the annoying heat, dryness, and scurfiness of the extremities may be prevented or diminished, and the patient be not only comforted but his situation improved. A matter of the greatest importance is faithful, conscientious nursing; and where this service can be had from a qualified member of the family the best result will probably be obtained, and thus risk of injury to our patient from the ignorance of the inexperienced, or the presumption and self-sufficiency of a professional nurse, will be avoided. Whilst it is proper that the wishes of the patient, when reasonable, should be gratified, it is, as a rule, best that company be excluded from the chamber, for out of a number of visitors it often happens that some one lacking in prudence, intelligence, or forethought gives expression to that which may prove a source of much mental inquietude and serious injury to the patient. As in health a calm, cheerful frame of mind is, by its influence upon the organs of secretion, conducive to a proper performance of the digestive and other functions, so in disease does a similar relationship obtain. The necessity, then, in typhoid fever, with its low vitality and inordinate waste of tissue, to avert every mental condition that might interpose an obstacle to the reception and digestion of food, is obvious and of paramount importance. Every word, look, or line of conduct tending to engender unpleasant or despondent emotions should be sedulously avoided, whilst all that is encouraging, cheerful, and hope-inspiring must be summoned to our aid in conducting the case to a favorable issue.

The medicinal treatment of typhoid fever can with difficulty be deduced from any certain appreciation of its causation and pathology. We are consequently compelled to act upon general principles, and treat conditions, so far as these may be learned, from symptoms of unequivocal signification. It would be out of place, on this occasion, even to name a tithe of the various agents employed for the cure of this malady, nor is it intended to dwell long upon this subject.

The asserted value of excessive doses of quinine, or the use of the cold bath for the arrest, *in limine*, or the utility of the sulphites and other agents for the modification and rapid cure of typhoid fever, are not generally accepted as well-established facts, nor do we think the profession errs in hesitating to concede the potency of specifics in a disease of this character. We have in this affection several conditions of primary importance to contend with

demanding especial attention; and, fortunately, we have at command, in these cases, medicinal and other agents often of great power in the amelioration or removal of the pathological state involved. One of the conditions alluded to is delirium. When this is merely occasional, transitory, and occurs only upon arising from sleep, it may not be regarded; should it, however, be more decided and persistent, coming on early in the attack, in a strong subject, a few leeches behind each ear, cold applications to the head and sinapisms to the lower extremities, may be employed, and, if no diarrhoea be present, several grains of blue pill, or calomel and rhubarb, should also be given, to procure one or two free evacuations. Where the patient is rather weak in constitution, with but little heat of the forehead, or in the latter stage of the disease, when the vital power is low, warm applications to the head will sometimes prove more efficacious than cold, and in this case alcoholic stimulus ought to be given in such amount as the condition of the patient and the effect produced may render necessary; should this fail, recourse must be had to opium or some of its preparations. Protracted wakefulness is a common, greatly injurious, and often difficult condition to obviate or remove. A few hours of natural sleep each night restores, probably, more than anything else the worn and exhausted energies of the patient, and contributes greatly to his recovery, so that it is of the utmost importance to guard against every agent that might in the least disturb the equanimity of his mind, especially during several hours previous to the usual time for sleep. Should the want of sleep become, as it easily may, alarming, and the ordinary anodynes fail to relieve, morphia alone, or, if there be much arterial excitement, combined with a small dose of tartar emetic, may be given cautiously, yet bearing in mind that morphia, when it is borne well, is more likely to produce the desired effect in one or two rather large doses than in small and oft-repeated portions. If these means fail, an injection of a small teaspoonful of laudanum in half a gill of thin starch for an adult may be used, and where much diarrhoea is present this had better first be tried. As protracted delirium or coma frequently leads to retention of urine, the physician should, by occasional examination, satisfy himself regarding the state of the bladder: otherwise serious injury may result from neglecting a timely use of the catheter. If diarrhoea be slight, the patient young and vigorous, and able to take a moderate amount of food, it is not requisite suddenly to arrest it; under opposite conditions exhaustion must ensue unless it be checked. For this purpose the stronger vegetable astringents, or the mineral acids, sulphuric or muriatic, should be employed, and, if insufficient, opium by the mouth, injection, or in both ways, and in such amount as the exigency of the situation may demand. If tympanitic distention accompany the diarrhoea, spirits of turpentine and tincture of opium in combination should be given, or turpentine injections; and care must be taken that the patient receive no flatulent food. If hemorrhage supervene, opium and acetate of lead should at once be prescribed

internally, a strong injection of the same kind administered, and the patient enjoined to remain perfectly quiet.

In every disease of typhoid character and of long duration, such as that under consideration, a principal object is to give such support as may tend to prevent the vitality of the organism from descending so low that little hope of recovery could be entertained. To effect this purpose, tonics and stimulants must be resorted to. In this point of view quinine holds the first place as a medicinal agent, and is generally most useful when given in three- or four-grain doses every four hours. The mineral acids are also found useful, especially when diarrhoea is present. As a stimulant, carbonate of ammonia has long been held in repute by many physicians, whilst a smaller number give the preference to the spirit of turpentine; and the estimate placed upon the latter by Dr. George B. Wood and others in typhoid fever and kindred conditions is, we think, deservedly high. It is most useful in the middle and latter stages, when tympanitis so often occurs, and, although not palatable, is apt to agree well with the stomach.

It would answer no important purpose to cite and comment upon a multitude of inferior tonics and stimulants finding place in the *materia medica*, as it is generally conceded that the most natural, useful, and trustworthy means of support is found in the proper use of suitable food and drink. But here, unfortunately, in a matter of vital importance, arises a difficulty; for, whilst practitioners do not differ greatly in regard to what is proper food, they are often at variance in reference to the quantity required within a certain time and under similar circumstances; nor are they in accord as regards the amount of alcoholic stimulus to be given within certain limits of time, if, indeed, its use should at any time be permitted. If, in this connection, we revert for a moment to the practice of physicians from the days of Sydenham until a somewhat recent period, may not the retrospect justly occasion surprise and mortification? It was not the custom then to insist upon an amount of food that could not fail to oppress the stomach and impair still more the power of digestion. So, too, in the use of ardent spirits or wine, the rule was to watch its effect, and, when this was beneficial, as evinced by a slower, softer, and fuller pulse, a gentle moistening of the skin, a calmer breathing, and a more tranquil condition of the nerves, they continued to use it, uncontrolled by ultra views,—the offspring, perhaps, of a morbid conscientiousness in regard to the use of intoxicating liquors even as a medicine.

An excessive use of alcoholic potions, unless by Dr. John Brown and a few other erratic spirits of that day, was not common in disease, neither was there in its use the same disregard of the state of the vital powers as we occasionally see at the present time.

The discrepancy of opinion and practice referred to is practically an unfortunate one. Typhoid fever, distinctively marked as its typical features are, is yet in its general character a representative pathological state, and if the extremes of practice on either side

be alone correct, consistency would seem to require their adoption in other affections distinct in origin and nature. But there is more than a doubt in the minds of most physicians regarding the propriety of ultraism in medical practice. By the general consent of mankind, it is admitted that safety and truth are commonly found in the middle path, and whilst the daring extremist in either medical, surgical, or obstetrical practice may present, for our admiration, an occasional brilliant success, he is, in the general statistical result, left far behind by the more cautious and logical conservative.

In regard to a choice of food, physicians are generally agreed that milk, beef- or mutton-tea, and the essence of either, made directly from the meat, or well-prepared soups, should constitute the chief nourishment of the patient; whilst he may be permitted, for a change, the use of mild farinaceous articles; these agreeing, sometimes, better than a continued use of the former. The amount to be given at once, and the frequency of repetition, can best be determined by the physician; yet the patient, if at all intelligent, should be consulted upon this point, and care must be taken that during the night he is not so often importuned to take food that sleep is effectually banished. It will sometimes happen that the patient, in a somnolent, listless state, will, on all occasions when food is offered, open his mouth, as it were, automatically, and receive, swallow, and also retain it. This has too often been taken as proof of a large amount and frequent repetition being requisite, and thus inordinate quantities of food are given, far beyond the actual digestive power. That such practice is injurious cannot well be doubted, for it is to be remembered that each pathological state has its own special provisory and reservative corpuscular actions, obscure in their intimate nature, it is true, yet visible enough in their effects, and not to be disregarded. Whilst upon this point, it may be proper to state that the opposite plan of giving to a patient in typhoid fever a minimum of food is, in general, still more objectionable and injurious, but, fortunately, is not often practised.

Under the influence of a very few eminent physicians, alcoholic stimulation had run to excess until a somewhat recent period. In an uncomplicated and mild case of typhoid fever, very little or perhaps no stimulus may be required. Where inflammation, especially of the brain, occurs, it is inadmissible, unless in exceptional cases. But a difficulty here presents itself; for it is sometimes almost impossible to decide, though the symptoms point strongly in that direction, upon the existence of inflammation. The greatest caution is here necessary in the use of stimulus, and prudent delay is often the safer practice. Where prostration, actual or threatened, ensues, stimulus is often productive of the greatest advantages, yet should be given solely with reference to its effects. It is best to suspend its use as soon as may safely be done; its too protracted employment tending to injure the digestion and thus prolong the convalescence, or to create a desire for its habitual use.

But this introduction has already exceeded the limit at first intended, and must now be brought to

a conclusion in expressing the hope that, although nothing new has been presented to your notice, some casual remark or other may have recalled to the minds of members and may lead to the expression of some fact, observation, or deduction of practical value regarding the diagnosis, prognosis, and treatment of typhoid fever.

A REPLY TO THE ARTICLE BY JOSEPH R. BECK, M.D., ON THE USE OF IODIDE OF POTASSIUM IN SYPHILIS.*

BY EDWARD N. BRUSH, M.D.,

Buffalo, New York.

AS Dr. Beck, in his article, declines any scientific controversy upon the subject of his paper, I will not at present indulge in any such discussion; neither will I, at this time, exhibit any "overwhelming statistical statements." This article has been too hastily prepared to allow the employment of either mode of controversy. I will, therefore, simply glance at what Dr. Beck endeavors to show, and strive to point out certain indigestible portions of the "food for contemplation" which he furnishes in the two cases cited. Unfortunately for the stability of his theory, he has presented in these two cases nothing which shows that the use of the iodide of potassium in the *earlier* stages of syphilis is of equal or more value than the employment of mercurials.

Had he presented a case which proved that the iodide of potassium did not, as he says mercury does, "act too quickly," his paper might have been entitled to more consideration. He says, "We are well aware of the fact that, under the use of mercurials, secondary manifestations may be rapidly dissipated, and we have been enabled, owing to this fact, to discharge our patients in a few weeks without spot or blemish. But, alas for this treatment! we have in *every case* only succeeded in *masking* the disease. . . . We will surely have to deal with tertiary manifestations."

At the very outset of his paper I have to criticise his treatment. He says that mercury acts too quickly, and that by its use we are enabled to *discharge our patients in a few weeks*. Herein lies the fault. I have been taught to believe that the administration of mercury should be continued for months rather than weeks, and have looked upon a course of mild mercurial treatment extending over a period of from fifteen to eighteen months as essential in every case. When this course is pursued, mercury will not be found to act too quickly, and, in a vast majority of cases, tertiary manifestations, if present, will be of a slight and insignificant character. When these are present, Dr. Beck himself is not a more earnest advocate of the use of iodide of potassium than I am. But even in such instances I shall continue to believe, with Dr. Sturgis, that the administration of mercury is not without value.

1. In regard to Case I., the doctor's report leads me to believe that he was treating a case of tertiary

* Philadelphia Medical Times, March 13, 1875, vol. v. No. 176.

syphilis, in which case no one will dispute with him the value of the treatment which he pursued. I think that even Dr. Sturgis, whose views he criticises, will agree with him in that respect. This being the case, he has only shown additional evidence of the value of the iodide in the tertiary forms of syphilis, and has not disproven the efficacy of mercury, *properly* administered, in the early stages.

2. In reference to the same case, he says, "This case had its origin in what certain self-so-called leaders in syphilography are pleased to denominate 'chancroid.'" I am very much interested in the subject of the unity or duality of the venereal poison, and am anxiously looking for facts, but I am compelled in this case to ask what may seem an impertinent question: How do you know? The doctor gives us no evidence that he saw the case before it fell into his hands, as reported. This being the case, his statements must be based on the testimony of the patient, and he certainly must know, after seeing so many cases as he would have us believe, that this is very poor testimony to go by. This same objection holds in regard to Case II. The sore which was contracted in 1851, he says, was *soft*. Again, How does he know? I must beg of him when he gives us that promised review, in order to make it exhaustive, as he says he will, to give his authority for saying that a sore is hard or soft, or, as he seems to prefer it, a chancre or chancroid. If he treated the initial lesion in 1851, he is in a condition to testify; if not, unless his data are obtained from a competent physician who did, his evidence cannot be taken by those who want only *solid*, well-proven, and *well-observed* facts. It may be also said in regard to this case, as of Case I., that the dispute does not lie upon the treatment of tertiary syphilis without mercury, as in many instances I believe that it can be done successfully. The question is this: Can mercury be dispensed with in the treatment of syphilis? Dr. Beck's two cases afford no proof *pro* or *con* on the question. He simply reiterates what the merest tyro in syphilography ought to know, that iodide of potassium is an excellent remedy in the tertiary manifestations of the disease. How much more violent these manifestations would have been had no mercury been used, in the two cases cited, he leaves us to conjecture.

What results might have been expected had the non-mercurial treatment been pursued *from the first*, he fails to show by illustrative cases, and in just this failure lies the weakest point of his article, so far as establishing his theory is concerned.

In conclusion, Dr. Beck's test of the cure of his patient by the production of iodism by the administration of ten-grain doses a year after all treatment has ceased, seems open to many objections. It is a well-known fact that a patient at different times, and under different circumstances, will not tolerate the same amount of iodide of potassium which he will at others. Ten or fifteen grains will produce iodism in a patient who has not taken it for some time, when a short time previous one hundred grains have been administered three times

daily without producing any unpleasant symptoms. In regard to the use of large doses of the iodide, I heartily endorse all that the doctor says.

8 SOUTH DIVISION STREET.

NOTES OF HOSPITAL PRACTICE.

PHILADELPHIA HOSPITAL.

SERVICE OF PROF. H. C. WOOD, JR.

APHASIA, AND PARALYSIS OF RIGHT ARM.—AUTOPSY.

LIZZIE L., single, æt. 60; Ireland; very temperate; been in this country twenty years; says her health was always good previous to her attack; never had epileptic fits. Family history good. A year previous to the time of her admission, she woke one night and found that she had lost power in the right arm. She suffered no pain at the time, no headache, no aches in the bones, no sore mouth or tongue such as might have followed an epileptic convulsion. The following morning she discovered that she had entirely lost the power of speaking, although the idea of speech seems not to have been interfered with. After the attack she remained in bed a couple of days; not that she could not get up, but at the desire of her family. No physician was called. She remained at home for about a year, her arm still paralyzed, and with no improvement in her speech. During this time she had a number of epileptiform convulsions, which seem mainly to have affected the right arm, but never had any headache. At the end of the year she entered the house.

On her admission, November 15, 1874, she appeared pretty healthy, the hearing not at all impaired in either ear, the eyesight good; ophthalmoscopic examination negative in results. No apparent paralysis of facial muscles. The left corner of the mouth possibly a little drawn. When told to protrude her tongue, could not do it, nor could she put the tongue to the roof of the mouth; she could, however, lick her lips. She pronounced the labials very well; the linguals were managed with more difficulty; *r* and *l* were altogether beyond her. She could swallow very well, and had never bitten her tongue in eating. She had decided aphasia, mainly amnesic, but slightly ataxic in character. This aphasia was nearly perfect, as she was able to repeat most words after a person; but her own vocabulary was confined to yes and no and the interjections. She had great loss of power in right arm, but the power of the leg on that side seemed unimpaired. The sensibility of right arm about half that in left. The electro-sensibility the same. Electro-contractility also the same,—about half in the right what it was in the left. Her spirits were good at all times excepting when religious topics were introduced: when these were touched upon, however remotely, she burst into a paroxysm of tears.

She was ordered gr. $\frac{7}{8}$ phosphorus (Bullock & Crenshaw's granules) thrice daily, with an iron tonic.

Shortly after admission, she became excited by a visit from her sister, and was thrown into an epileptic convulsion, which at first pervaded the whole body, but in about a half-minute subsided, except in the right arm. The patient came to herself sufficiently to endeavor to reduce the spasm in the right arm long before it had subsided. After this she slept for some hours.

February 19, she had a second convulsion, which, as before, affected chiefly the right side. A full minute after the general spasm had ceased, the patient sat up in bed grasping her right hand (which was closely shut, with the thumb turned in), and endeavored to control the spasm.

March 5, the patient wished to leave the house, and her condition was as follows: speech very much improved, the patient being capable of making herself understood with considerable difficulty, but much more readily than when she entered. She could say *s* perfectly, and *r* tolerably. Her right arm was almost as strong as the left; the sensibility, electro and otherwise, not improved. She said, "Terrible times in my ward," with very good pronunciation.

Her spirits were still good, and religious topics were approached without exciting her in the least. Same treatment as above has been continued to the present.

March 6, 1875, very unexpectedly, before she had left the house, the patient died. She had been pretty well the morning of her death, when symptoms of collapse suddenly supervened. She lay with body bathed in a cold sweat, face pinched, pale, tongue dry, pulse 110, respiration 24. She was unable to speak, but seemed perfectly sensible, and, on being asked to do so, she indicated the abdomen as the seat of pain. She grew rapidly weaker, and died in the course of an hour, without a convulsion or even a twitch of the face. It should be added that the right arm seemed totally powerless after the collapse set in.

Post-mortem, three hours after death.—Body emaciated, feet slightly œdematous, blood fluid, lungs perfectly healthy. Heart eleven ounces, and in a condition of advanced fatty degeneration, as revealed by the microscope; arteries extensively atheromatous throughout. Liver cirrhotic, and somewhat "hobnailed." Kidneys of the fatty, contracted type. Substance of skull very brittle. Brain, fifty-two ounces, but much smaller than the cranial cavity, so much so that the dura mater could be picked up in folds. There was absence, however, of the usual compensating serous effusion. The pia mater was somewhat cloudy, but not adherent to the dura. There was a slight serous effusion under it on the convexity of the brain. At the base and under the cerebellum, and between it and the medulla, there was slight but distinct extravasation of blood. On the surface of the left hemisphere there was an irregular spot, apparently the seat of a former clot, measuring three-fourths to one and three-fourths inches, to which the membranes were adherent, and which was depressed, soft, and of a yellowish hue. This area began above, at a point opposite the anterior central convolution, followed the course of the vertical branch of the fissure of Sylvius, and affected chiefly the upper part of the third frontal convolution, touching the extreme upper part of the second frontal convolution, and involving the lower anterior angle of the operculum. In the fissure of Sylvius the membranes were stained and adherent. The convolutions of the island of Reil were almost entirely effaced. The brain-substance immediately adjacent to the eroded island was not softened, neither was it stained with hæmatoidin.

TRANSLATIONS.

DISCUSSION UPON THE EFFECTS OF NITRITE OF AMYL.

—At a recent meeting of the Medico-Psychological Society of Berlin (*Wien. Med. Presse*, February 28), a discussion took place upon the effects of nitrite of amyl. Dr. Solger said that the flushing of the face produced by the inhalation of this remedy must be ascribed to a paralysis of the centres of innervation of the arteries supplying a certain area.

Other centres than those supplying the face are at times affected. He had himself experienced flushing of the hands and feet. He had used the nitrite in a case of unilateral clonic spasm in a child, without success. Chloroform used in the same case caused the

convulsions to disappear for some time. The effect of chloroform seemed to be antagonistic to that of nitrite of amyl. The vessels of the pia mater exposed in a rabbit under the influence of chloroform were seen to be contracted, while upon inhalation of the nitrite they became enlarged.

Dr. Jastrowitz had used the nitrite of amyl with good results in asthmatics, but in the case of melancholia and other forms of insanity without beneficial effect. Inhalation of the drug causes disagreeable dizziness. He would not, therefore, use it in cases of vertigo. His impression was that hyperæmia of the brain did not extend throughout that organ, since, in patients who had used the remedy for some time, hyperæmia of the optic papilla could not be observed either during inhalation or in the intervals. Dr. J. mentioned cases illustrating the danger sometimes attending the inhalation of the nitrite, and the necessity of caution in its employment. In these cases sudden collapse followed its use. He had subsequently met with Schüller's experiments showing that a marked contraction of the vessels of the pia follow the usual dilatation. He had also observed that certain patients voluntarily alluded to the fact that objects appeared of a yellow color subsequent to the use of the nitrite.

Dr. Mendel agreed with Dr. Jastrowitz as regards the local character of the hyperæmia produced. He had arrived at this conclusion by taking the temperature of the external auditory meatus, which remained unchanged.

Dr. Solger remarked that, as to vertigo, it is produced by various conditions, and there might be varieties of dizziness in which the nitrite would prove very useful. Schüller's experiments were worthy of careful attention. They proved that the inhalation of nitrite of amyl should not be abruptly, but gradually, broken off. He spoke of its value in those cases of epilepsy where sufficient warning was given by an aura, and related the case of a workman subject to such attacks, who was able to ward them off and continue his occupation by the expedient of keeping a small vial of the nitrite by him, which he made use of as soon as he was aware of the premonitory symptoms. He was in the habit of using, in hospital and private practice, certain sealed capillary tubes containing three to five drops of the nitrite, and wrapped in a bag. In this receptacle no evaporation or decomposition could occur. The patient carried one of these about with him, and when needed it could be broken by a movement of the hand almost instantaneously, the rag serving to retain the medicine for inhalation, and also to provide for its more gradual withdrawal.

Dr. Sander remarked that in his cases of sudden collapse the inhalation had been withdrawn gradually and the chamber was full of the nitrite vapor.

Dr. Bernhardt said that the effect of the nitrite would not show itself so quickly in increase of temperature in the external meatus; even if a thermometer were placed in the brain or under the pia mater, it would be doubtful if a rise could be observed: besides, it was certain that the vessels of the pia become enlarged, and these supply the brain.

Dr. Mendel said, on the contrary, that the effect of chloral could easily be ascertained in the rise of temperature in the ear.

Dr. Westphal protested against drawing too hastily diagnostic conclusions from a few positive or negative results of the inhalation of nitrite of amyl. X.

THE NATURE OF CHRONIC ALOPECIA.—Dr. J. Pincus (*Berliner Klin. Wochen.*, February 1) says that nineteen out of every twenty cases of baldness are due to the disease known as alopecia simplex, alopecia furfuracea, or calvities senilis and prematura.

Two views of the pathology of this disease have been held: one ascribing the accompanying atrophy of the cutis to a primary wasting away of the vessels; the other, to an atrophy of the peripheric nerve-fibres. Dr. Pincus believes that a condensation of the connective tissue of the lower layers of the cutis takes place in the earlier stage of the disease, accompanied by a loss of typical length on the part of the hairs, but not in their diameter. At the same time certain alterations take place in the amount and character of the glandular secretions, possibly depending upon the irritation of the condensing connective tissue surrounding them.

In the second stage, the hairs become thin, and this is particularly noticeable in the thickest and woolly hairs, whose roots are situated deeply among the condensing tissue. In the first stage of the affection, the whole head is equally affected, and the hair becomes equally thinned throughout. In the second stage, it is the vertex and forehead which are most severely affected, and, while the sides remain stationary, the disease-process goes on in these localities. By the slow and gradual destruction of the nerve-fibres by the condensing connective tissue, the relative sensibility of the skin is much diminished in the affected parts, but without pain.

In the earlier stages of the disease, Dr. Pincus recommends the use of a solution of caustic potassa or soda, one part to two hundred and fifty or five hundred of water, or sodii carbonas, four parts to one hundred to two hundred, or sodii bicarb., four parts to fifty to one hundred and fifty. Of these solutions, two or three tablespoonfuls are to be rubbed into the head for several minutes, at first daily, afterwards oftener. Unfortunately, the prolonged use of this remedy, although of great service, yet has the drawback that it discolors the hair. If it is wished to avoid this, a solution of iodide of potassium, one or two parts to one hundred, will act favorably, though not so rapidly as the former.

In the latter stages Dr. Pincus uses stronger solutions of these alkalies, with a very weak solution of corrosive sublimate, one part to seven thousand five hundred. He has used all the various irritating and astringent washes, oils, and pomades, without success. X.

CROTON-CHLORAL HYDRATE.—Dr. Weill (*Bull. Gén. de Thérap.*, March 15), who has been making investigations upon this substance, concludes as follows: Croton-chloral hydrate is a hypnotic like chloral; usually in a smaller dose. It exercises an especial action upon the sensory cranial nerves. In a moderate dose it has not the same action upon the movements of the heart and upon the tonicity of the muscles, nor does it diminish respiration or reduce the temperature to the same extent as chloral. In excessive doses it causes death by arrest of respiration. The lesions observed after death in animals consist in an intense hyperæmia of the meninges, particularly those of the encephalon.

Its therapeutic employment is indicated: (a) in neuralgias of the trifacial; (b) in other neuralgias and against the phenomena of pain in general; (c) in spasmodic affections of the nervous system; (d) when the use of chloral is not safe on account of disease of the heart; (e) to calm the cough in certain chronic affections of the respiratory tract; (f) to procure sleep.

The contra-indications to its employment are an inflammatory condition of the digestive tract, and a predisposition to encephalic congestions.

Its taste is more disagreeable than that of chloral, and it is absolutely necessary that it should be masked by some corrigent; extract of liquorice seems to be the most appropriate. It cannot be administered hypodermically.

As to the dose, M. Weill says, "If it is only desired to

procure sleep, seven to fifteen grains will be sufficient in the great majority of cases; that is, if the suffering is not so severe as to render a large dose of some narcotic absolutely indispensable. In this case, thirty, forty, or sixty grains may be administered at once, and even more if necessary. In case of neuralgias, the English method is applicable, one, two, four grains repeated every quarter-hour, half-hour, or hour until relief is obtained, and it is often astonishing with what rapidity this result ensues." X.

EPIDEMIC PAROTITIS.—Dr. S. Pollack (*Wien. Med. Presse*, March 21) has had an opportunity for the first time in twenty-eight years' practice of observing this interesting pathological occurrence. Inflammation of the parotid, usually occurring only sporadically or as a sequel of some previous acute infectious disease, as scarlatina, was here observed quite isolated, as an epidemic.

More than sixty cases came under Dr. P.'s care in the course of six to eight weeks. The disease chiefly attacked children and youth of both sexes and in all classes; appeared in several families upon the same day, attacking usually individuals only. The intensity of the attack varied. In some cases the swelling was moderate, in others, as large as the fist, preventing chewing or opening the mouth, and causing much pain. When an examination could be made, the tonsils and isthmus faucium were found intact. Fever only occurred in the severer cases. The duration was from three to eight days, ending in resolution. No other symptoms were present, and scarlatina did not appear at any time. The treatment consisted simply of rest, with hot or cold applications, as the case required. X.

BACTERIA IN NORMAL BLOOD.—Dr. Kolaczek (*Centralblatt für Chirurgie*, No. 13, 1875) has repeatedly found Bacteria, such as are considered to be characteristic of certain diseases, in normal blood. Under a power of from one thousand to fifteen hundred diameters, certain diminutive round bodies are observed, having sharp contours, and somewhat refractive. They are sometimes arranged chain-fashion, usually two together, occasionally three, and maintain a rapid oscillatory and migratory motion, while the blood-corpuscles and their molecular derivations in the same field remain perfectly quiet. Two of the minute globules are sometimes joined together so as to look like a single one, and occasionally a couple of these double spheres join, to form a rectangular figure, possessing the above-mentioned peculiar movements.

Kolaczek's experience in the study of Bacteria leads him to class these globules as Bacteria or micrococci, and he therefore concludes that either Bacteria are found in all blood, or that, in spite of every precaution, certain of these minute bodies enter the preparations from the external air. He thinks that it is possible they may be introduced in the food, and has examined the excretions with great care, in order to see if they could be discovered in these.

The urine was examined by passing the stream, towards the end of its voidance, into a reagent-glass which had been cleaned with solution of potassa and sulphuric acid and boiled in absolute alcohol. From this it was immediately drawn by a tube prepared similarly, and of which the closed capillary end had just been broken open, while the other end was stuffed with cotton. It was then examined on a slide, and with a cover prepared in like manner. The result showed micrococci, which could no more have been imported from the air than those found in the blood. Dr. K. purposes undertaking further researches upon this subject. X.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, APRIL 24, 1875.

EDITORIAL.

THE MEETING-PLACE OF THE AMERICAN MEDICAL ASSOCIATION IN 1876.

AS is well known, the medical profession of Philadelphia, through some of its most representative men, partially invited the American Medical Association to meet at this place next year. This, under the circumstances, is so eminently proper that we believe it has been acquiesced in generally, and, if we are not misinformed, throughout the country the members of our profession look forward towards visiting Philadelphia during the Centennial. Since last year, however, the idea of a Centennial Congress has ripened into the action of which we take note in another column, and, if Dame Rumor be not a liar, it is intended, by some of those who are supposed to be especially powerful in this city and in the American Medical Association, to sacrifice the latter to the supposed interests of its foreign sister. Confirmation of this rumor is furnished by the fact that neither of our learned societies has as yet taken any official action in regard to inviting the American Medical Association here.

Since the Association has refused to recognize the College of Physicians,—the society to which of all others it owed its origin,—it is not to be wondered at that the College observes a dignified silence; but it is astonishing that the County Medical Society has not ere this passed a formal resolution of invitation. To our thinking, it is already committed to such action, and if it does not go on in the work it will

stultify itself and the profession of Philadelphia before the country.

It is not necessary here to repeat the very obvious reasons there are for holding the meeting of the Association in this city in 1876. Our readers are neither blind nor foolish. It may be worth while to say a few words in regard to the reasons probably assigned by those who are said to be planning to get New York appointed as the place of session.

In the first place, it is affirmed that the regular meeting-time of the Association is such that our whole city will be in 1876 just then swallowed up in the confusion and tumult incident upon the opening of the Centennial. This is readily met by altering the time of meeting to June or some other month.

In the second place, it is stated that it will not do to have two associations meet here at one time. Of course not; but is there not more than one week in the year?

Again, it is objected that delegates will not come twice to the same city, and that at any rate the city will all summer long be so crowded as greatly to inconvenience both visitors and hosts. Of course our city will be crowded; but it is to be hoped our hospitality will be sufficiently elastic to embrace all who come, and we have no doubt that, if no other shelter offers, the profession in their private homes can afford sufficient protection from the storms of midsummer.

There is, of course, some force in the obvious difficulties in the way of meeting; but, not to occupy too much space with this discussion of the matter, it appears to us that all these difficulties would be avoided by leaving the time of meeting for 1876 to be fixed and announced by a local committee, it being understood that they should so arrange that the sessions of the American Medical Association should terminate on a Friday or Saturday and those of the Centennial Congress should commence on the subsequent Monday. No one will be able to exhaust the great exhibition in the afternoons of a single week, and delegates to the first association could readily hold over for the second.

ALMOST A MURDER.

THERE has recently happened in Scotland a curious case of suspected murder, involving such nice points in medical jurisprudence, and illustrating so forcibly the necessity and value of trained experts, as to justify a sketch of it in this place. As the result of such a transaction in this country, where physicians are so often selected by the gov-

ernment because they know nothing about what they are called to investigate, the innocent victim of circumstances would very probably have been hung, or at best involved in an anxious trial, with, likely enough, professional episodes as disgraceful as those which so often adorn our important criminal court proceedings.

A lad, whilst passing along a street in Edinburgh, about one A.M., September 24, 1874, stumbled over the still warm, half-naked body of a man, lying with extended arms across the footpath. The police, being summoned, found that the man had evidently fallen or been thrown from a still open window in a third story. Entering the house, they ascended to the room, and, striking a light, found a second man in the bed, wrapped in the bed-clothes, and, as they thought, feigning sleep. The landlady of the house had already informed them that two men occupied the room together; that one of them, named Stoddart, had been in Australia, and had subsequently become insane, and that the two had quarrelled seriously a day or two before. On shaking Stoddart, he awoke, and denied any knowledge of the whereabouts of his comrade, stating that they had made up their disagreement, and had both gone to sleep sober the night previous.

The pillow of the bed was spotted with blood. The hands of Stoddart seemed damp, as though recently washed, and on one of them were an abrasion and some spots of blood. From the bed to the window was a continuous line of spots, gouts, and pools of blood, and lying in one of the latter was a case-knife covered with blood. The police, believing that Stoddart had either thrown his companion from the window or had attacked him so violently that he had leaped from the window, arrested him, and locked up the room.

Dr. Joseph Bell, who, in the absence of the official medical officer, Dr. H. D. Littlejohn, was first called to the case, decided against the theory of murder, because he believed that the peculiar spotting of the bed-clothes was such as could only have been produced by the spray of a sudden violent cough or sneeze. There were several wounds on the head, but these he decided to be not cuts with a knife, but lacerations due to the fall. He thought that the deceased had been seized with a hemorrhage from an aneurism or from a phthisical lung, awakened with the violent cough of strangulation, rushed to the window, and inadvertently leaned out too far.

The police did not accord in opinion with Dr. Bell, but Dr. Littlejohn, on inspecting the apartment, came to the same decision as the first professional expert. Taking advantage of a fact pre-

viously noted, that spots of blood not visible by daylight become apparent by candle-light, he was enabled to determine that a spray of blood had been thrown upon the wall-paper as well as upon the bed. At the autopsy, the chest, abdomen, windpipe, throat, cervical spine, and cranium were successively examined, but nothing found that could in any way be considered as having been before the fall a source of hemorrhage into the air-passages. Instead of giving the matter up, the physicians finally removed the upper maxillæ, when it was found that the left middle turbinated bone had its mucous membrane ruptured in two places about the size of millet-seeds; in these openings there were minute coagula. As it was ascertained from the relatives of the deceased that he was subject to violent epistaxis, and as a neighbor was finally found who, looking out of the opposite window, saw the man flash past and heard the yell and the heavy thud on the pavement, and who was absolutely certain that there was no noise or struggle in the room, to which her attention was drawn by the open window, the police were finally satisfied, and the prisoner was discharged, fairly freed by expert skill from a most embarrassing position.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

AT a conversational meeting, held Wednesday, February 10, 1875, at 8 o'clock, P.M.,

VICE-PRESIDENT, Dr. EDWARD WALLACE, in the chair,

Dr. W. T. TAYLOR presented the following history of a case of obstruction of the bowel:

"On Thursday morning, February 4, 1875, about two o'clock, I was called to see P. R., a German, aged 71 years, who was suffering with pain in the bowels, in the left iliac region, attended with some sickness of the stomach. For a year past he had been occasionally affected with bilious colic, followed by jaundice, so that I thought the present attack was similar, and gave him an emetic to empty the stomach, followed by an anodyne carminative.

"On making my morning visit, I found that the vomiting had continued at intervals, and that he had ejected a considerable quantity of a greenish liquid of an intensely bitter taste, but the pain had not abated. The anodyne was continued, and lime-water, with milk-punch, administered, together with a purgative containing blue mass, podophyllin, ext. hyoscyam., and ext. colocyn. comp. I also applied a sinapism to the abdomen. He had some fever, a furred tongue, and a full pulse.

"As the purgative had not operated during the afternoon, I gave an injection of castor oil and molasses with warm water, followed by large injections of warm water and soap, but they came away with very little fecal matter. As the soreness had not subsided in the left iliac region, one dozen leeches were applied, and the abdomen covered with a warm mush-poultice; he also took one grain of blue mass and one-half grain of opium every two hours. The pain diminished somewhat during the night, but the sickness and vomiting

occurred at intervals of from one to two hours, and the ejecta had a perceptible stercoraceous odor; the bowels had not been opened.

"On Friday, February 5, Dr. R. Stewart saw the case with me, and we added one-half grain of ext. belladonna to the pills of blue mass and opium, which were continued as before. An injection of castor oil and turpentine with ten drops of croton oil was given, with no better effect. The fecal vomiting still continued as before. In the evening I gave very large injections of castor oil and thin gruel, as much as could be thrown in the colon: the warmth was agreeable to the patient, but did no other good. The vomiting continued at intervals until his death, which occurred on Saturday morning at seven o'clock.

"On making a post-mortem examination, I found the body well nourished, containing a large quantity of fat in the omentum and mesentery. The stomach and bowels were empty until I reached the ileum, where a semi-solid mass of the size of a large horse-chestnut was found, resembling it also in color. Above this mass the intestine was of its proper calibre, but below it was quite small, and paths of inflammation extended upwards some twelve or eighteen inches towards the jejunum. With this exception, the bowels were completely empty, both above and below the obstruction. I did not discover any inversion of the bowel, as I expected, nor any hernia, but was much surprised on examining this mass to find it was fecal matter with a central nucleus."

The fecal mass was referred to the Committee on Microscopy. The Chairman, Dr. Tyson, reported as follows:

He had examined the concretion, and found it composed of numerous concentric layers of fecal matter, with a small nucleus of a harder shell-like material, probably derived from the food. In this respect it corresponded with the concretions which are a well-known cause of fatal peritonitis, and which are never the cherry- and date-stones which in external configuration they so closely resemble, and with which they have been confounded. He had recently made three post-mortem examinations where these concretions were the cause of death, and in each instance they exhibited this structure. Only a short time ago he had met a statement of Sir William Jenner, from the Chair of the Pathological Society of London, to the same effect, that these concretions were always fecal matter with a nucleus. In this instance, however, the concretion was larger, at least an inch in diameter in the dry state, very stinking, and clearly fecal matter. A section exhibited with beautiful distinctness the laminae entering into its composition, and the successive layers could be easily removed. The entire mass was exceedingly friable.

Dr. J. G. HAMILTON then read a paper on the "Diagnosis, Prognosis, and General Management of Typhoid Fever."

Dr. STETLER asked the doctor whether he recommended three or four grains of quinia every three or four hours during the twenty-four: if so, he thought it was too much for tonic purposes. He would not be willing to give it in such doses in typhoid fever, for fear of increasing the trouble in the bowels. When attending the Pennsylvania Hospital, about twenty years since, where this disease was very successfully treated, not more than eight or ten grains were given per diem.

Dr. HAMILTON said the paramount importance of sleep was obvious, and therefore he was in the habit of discontinuing the doses of quinine or other ordinary tonics during the night, and thus the amount of quinine given in twenty-four hours would not be large. If the bowels were loose, opium or any other preferable medicine should be given.

Dr. WELCH remarked that perhaps the gentleman who

last spoke might not be aware of the extent to which quinine is used in the treatment of typhoid fever in Germany. He (Dr. W.) proposed to show that the doses recommended by the author of the paper just read, instead of being large, are indeed small in comparison with those administered in the hospitals at Kiel and Basle, and perhaps at other places also in Germany, where the so-called antipyretic treatment has been adopted in the treatment of all febrile affections.

It has been found that quinine, when given in large doses, will reduce the temperature of the body; and, acting upon the theory that typhoid fever produces death by reason of the long-continued high temperature of the body, some German practitioners have conceived the idea of administering quinine in the treatment of that disease in what they would style antipyretic doses. In order to obtain the desired result, quinine is used under the guidance of the thermometer; that is to say, if the temperature reaches or runs above 102° Fahr., quinine is given in sufficiently large doses to reduce the temperature to nearly the normal standard. To accomplish this, Liebermeister states that from twenty-two to forty-five grains are ordinarily required, all of which must be taken within half an hour, or, at the most, one hour. Liebermeister's method is to administer seven and one-half grains every ten minutes, until the desired amount is taken. It must be borne in mind that the object in view is to make a positive impression upon the nerve-centres, which cannot be done by quinine if given in smaller doses and at longer intervals. If the first dose does not sufficiently reduce the temperature, the next one is increased; or, on the other hand, if the first dose reduces the temperature to 98.5°, or below, which Liebermeister says is not a very uncommon occurrence, then the next dose is diminished. He also states that in order to maintain the good results of quinine it is necessary, as a rule, to repeat the dose every second day.

The same writer also describes another means employed in the hospitals referred to with the object of lowering the temperature of the body, and that is the so-called cold-water treatment. This consists in subjecting the patient to cold baths of 68° Fahr. Each bath is of about ten minutes' duration, and they are repeated, in severe cases, as often as every two hours, so that not unfrequently twelve such baths are administered within twenty-four hours, and as many as two hundred and over in the course of a very severe attack of typhoid fever. It is said, however, that in the majority of cases a much less number of baths will be required, especially if antipyretic drugs are made use of at the same time; as, for instance, four to eight per diem, and from forty to sixty in the aggregate, will ordinarily be found sufficient. Of course the thermometer serves here, as in the treatment by quinine, to show the length of time the lowered temperature is maintained. As soon as the temperature rises to 102.2° in the axilla, or 103° in the rectum, the cold bath is repeated.

The statistics of Liebermeister seem conclusive in proving the superiority of this treatment over what he calls "indifferent treatment." He shows that in the hospital at Basle, where of late years the antipyretic treatment has been energetically and systematically applied, the rate of mortality from typhoid fever has been reduced two-thirds. This, surely, is a very large reduction of the death-rate; so large that it seems incredible that it should be wholly due to the course of treatment pursued.

There is one very important point in connection with the treatment of typhoid fever which the author of the paper read to-night omitted to mention, and that is the disinfection of the stools as a means of preventing the spread of the disease. It is now generally admitted

that the discharges from the bowels of typhoid-fever patients contain the germs of the disease. This being true, the importance of thoroughly disinfecting the stools before they are emptied into a privy-vault or a similar place, where a rapid reproduction of these germs may take place, cannot well be over-estimated.

Dr. STETLER, in reply to Dr. Welch, said he had not heard that these large doses of quinine—forty to fifty grains per diem—had been tried in Philadelphia in the treatment of typhoid fever, and he hoped they never would be. He granted that you might reduce the temperature for a time by overwhelming doses of quinine, but he feared the effect, and preferred the old treatment to such hazardous methods.

Dr. W. R. BLACKWOOD stated that he had used quinia in a large number of cases, and had never seen injurious effects from its employment. In the South, during and since the war, he gave it frequently in doses as high as eight grains every three hours, with decidedly beneficial results. He did not administer it at night, but relied more upon food and alcoholic stimulants. He believed that rest and sleep were of more service at night than medicines.

Dr. C. F. WITTIG said that in his day, in Germany, they gave no quinine in typhus, while the infusion or decoction of Peruvian bark, occasionally combined with valerian root or serpentaria, was frequently employed to combat nervous disturbance. Entero-typhus, together with pneumo-typhus, belongs to a family of diseases that are caused by miasmatic agency. In the latter, the cerebral nerves as well as the respiratory mucous membrane are especially affected; in the former, the principal action of the poison is on the spinal marrow and the abdominal ganglia. Intermittent fever, in which the exhibition of quinine is so beneficial, being likewise a zymotic disease, we may readily infer the usefulness of the remedy in entero-typhus; in both of which it seems to counteract reflex action. The disease under discussion is therefore no mere enteritis (according to Broussais), but a poisoning of the blood, with intestinal irritation, the treatment of which requires the eliminating method, with due consideration of the local intestinal symptoms and the support of the vital forces.

Dr. W. T. TAYLOR remarked, in regard to the diagnosis of typhoid fever, that there might be languor, headache, epistaxis, pain in the stomach, and diarrhoea, but there is only one positive and characteristic sign,—the rose-colored spots, which, according to Louis, Wood, and other writers, may be few or many, scattered over the abdomen or breast. As smallpox, scarlet fever, and measles are distinguished by their eruption, so enteric or typhoid fever is known by its spots. In the treatment, medicine may be omitted during the night, but food and stimulants must be given at intervals to sustain the patient. The lecturer did not speak of the injurious effects of impure milk. He had not seen in his own practice any injurious effects that he could attribute to milk.

Dr. HAMILTON, in reply to Dr. Taylor, said he thought the regular use of food, and perhaps stimulus, was often imperative night and day. The more distinctive characteristics of the eruption in typhoid and typhus were alluded to in the paper. In perhaps one-third of his cases he had failed to discover any eruption.

Dr. ATKINSON asked whether he thought the fever could be aborted.

Dr. HAMILTON said he thought not.

Dr. STETLER asked Dr. Hamilton whether the prodromes are not the best signs to aid us in making an early diagnosis, and the other symptoms as they are developed mainly confirm it. He thought we could not hold the diagnosis in abeyance until the appearance of the rose-colored eruption. This, although very characteristic, does not always manifest itself. Most practi-

tioners are compelled to make a diagnosis before this period, except in very rare and obscure cases.

Dr. HAMILTON remarked that all the usual symptoms of continued fever could exist and give ground to regard the disease as typhoid, and yet it might not be of this character. The appearance of the eruption peculiar to the affection would remove all doubts more effectually than any other single pathognomonic symptom of the disease.

Dr. ESHLEMAN remarked that typhoid fever occasionally sets in as an intermittent. In this form he pushes the quinia, but when cut short he is unable to say positively that the case was typhoid. When we fail to abort this form, the case is positive against the assumption. We do meet with cases in children that yield to ordinary treatment, with or without quinia, in the course of a week, which we cannot well classify except as typhoid.

He is in the habit of stimulating freely when the pulse grows frequent and feeble, and when he finds stimulants to lessen the frequency and increase the force of the pulse. For the purpose of preserving the blood he gives, early in the disease, scruple-doses of the bisulphite of sodium, thrice daily. He gives turpentine early, with the effect generally of warding off the dry and chapped tongue. He likes the effects of cool-water sponging of the extremities. He does not regard typhoid fever in private practice in our city as at all fatal: though the temperature rises to 106° or 107°, the patient recovers.

SELECTIONS.

NAUNYN ON THE PRESENCE OF SUGAR IN NORMAL BILE.—At a meeting of the Königsberg (Prussian) Verein für Wissenschaftliche Heilkunde, held on March 9, 1874, Herr Naunyn made some remarks on his discovery that sugar is present in the normal bile of rabbits. In all the animals in whom he had made biliary fistulæ, he had invariably found sugar in the first drops of bile which escaped,—a proof that it must actually exist already in this secretion. The quantity of sugar in the bile secreted afterwards was, however, found to undergo a progressive increase. The importance of these facts in relation to vital (? normal) glycogenesis was also discussed, but the report in the *Berliner Klin. Wochenschrift* (No. 2) for January 11, 1875, does not mention the conclusions of Herr Naunyn.

[No mention is made of the tests employed, or of the precautions to avoid fallacies. At present the results of Dr. Wickham Legg's experiments stand in apparent contradiction; unless, after injury of the medulla oblongata, all the sugar escaped in the bile, instead of appearing in the urine.]—*W. Bathurst Woodman, M.D., in London Medical Record.*

SLOWNESS OF PULSE.—Mr. Pugin Thornton lately brought before the Clinical Society a case in which the pulse had at one time beat only 16, and for some weeks did not reach higher than 24 per minute. The patient was a young married woman, upon whom, in 1872, Mr. Thornton performed tracheotomy for syphilitic laryngitis. Her pulse at the time of the operation was 40, and it was not until six weeks later, when the tracheotomy-tube was removed, that the extraordinary slowness of her pulse was noticed. This infrequency had been accompanied by transient attacks of an epileptiform character. It appeared that in the summer of 1870 she was first seized with these fits, which at that time happened daily for about two months, the pulse averaging about twenty-four pulsations per minute. The woman, at the present time, is in good health, her pulse being constant at 48; but she is still periodically

obliged to take iodide of potassium to stop the recurrence of the laryngitis, which occasionally threatened. Mr. Thornton could not account for the curious phenomena, unless that the pneumogastric nerve might be presumed to be in some way affected by the specific poison.

Mr. Cullender said that in some cases of slowness of circulation the patient seemed to suffer from cold; but he had a patient recently in St. Bartholomew's who had a pulse of 32 only, whilst a more robust man there could not be. Another member stated that in one of the earlier volumes of the *Medico-Chirurgical Transactions* there was a case recorded in which the pulse ranged from 25 to 7. At the post-mortem the foramen magnum was so contracted that it would hardly admit the tip of the little finger; and there was hypertrophy of the superior cervical ganglion of the sympathetic nerve. Dr. Symes Thompson remarked that the late Mr. Hodgson had a pulse which rarely exceeded 32, and used to draw attention to the fact that a slow pulse might exist for years without the production of any manifest symptom.

Dr. Archibald Hewan informed the Society twenty years ago his pulse was 72. After great study it was found to be 55; from that point it had gradually decreased. Eight years ago it was 24. Then Dr. B. Sanderson traced it with the sphygmograph. He had never had a fit nor fainted, and could bear cold well. He had lately climbed a mountain several thousand feet high, and his pulse at the top was 40. His urine had not altered in any way; his digestion was very good, and he was in good health. Dr. Althaus said that Napoleon the First had a slow pulse, and always felt uncomfortable, except in the excitement of battle, when it would rise to 60. Dr. A. Hewan mentioned that he had had rheumatic fever eight years ago, when his pulse did not rise above 32. Eight weeks ago he had gout and rheumatic pains, when his pulse quickly rose to 64 and 68, and then fell slowly to 32 and 28, at which it stood at present.—*The Doctor*.

GLEANINGS FROM OUR EXCHANGES.

PLUGGING THE VAGINA IN PLACENTA PRÆVIA.—The *Irish Hospital Gazette*, March 15, contains an abstract of a series of papers by Prof. Charpentier, which have appeared during 1874 in the *Archives de Tocologie*. Dr. C., after giving a historical sketch of the condition and the various theories which have been advanced for the purpose of explaining it, gives considerable space to the question of treatment. He looks upon the plug as the treatment *par excellence*. It requires to be applied skilfully to be of any great use. Charpie or tow is the best material with which to plug, and, if properly applied, the author considers such a plug superior to any description of india-rubber bag which can be introduced into the uterus and inflated. The great point to attend to when plugging is to introduce enough of the charpie or tow, as much as a pound and a half of the former material being sometimes necessary. The bladder and rectum should both be emptied before we proceed to plug. Some practitioners dip the first pledget in a solution of perchloride of iron. This is not necessary. The charpie should be rolled into small balls, the first twenty or thirty of which should have small pieces of thread attached. Before being introduced they should be well covered with cerate. This renders a speculum unnecessary. The author lays great stress upon packing tightly the anterior and posterior cul-de-sac, but especially the latter. The success of the operation depends to a great extent on this being well done. The vagina itself should be filled with the small pledgets

until they appear externally. Then a handful or more of dry charpie is to be applied, and over that three or four compresses, the whole being fixed by a T-bandage. If this plug be well applied, there can be no hemorrhage. If the charpie at the vulva become moist, it is a proof that the plug is badly applied, and it should be removed at once and reapplied. To be of much service, the plug should be left in from twelve to twenty-four hours.

ON THE EXCRETION OF NITROGEN IN THE URINE.—Dr. I. Byrne Power (*Dublin Journal of Medical Science*, February) thinks that Dr. E. Reynolds's paper on the method and importance of estimating the total nitrogen in the urine has not met with the attention it deserves. The quantity of nitrogen excreted as urea has heretofore been taken, if not as an absolute, at least as a relative measure of the entire nitrogenous urinary excretion resulting from waste of animal tissue.

That it is not so was shown by Dr. Reynolds, who called the nitrogen present in the urine, otherwise than in the form of urea, "residual." Dr. Power gives the method devised by himself for ascertaining more accurately the point at which, in Liebig's method, the mercuric nitrate has decomposed all the chlorides and begins to precipitate the urea. He then adds a table of analysis of urine, made by himself, using his improved method of estimating the urea in connection with Dr. Reynolds's plan for ascertaining the residual nitrogen. The results of these analyses show residual nitrogen in eleven cases, in amounts showing a ratio of $\frac{1}{10}$ to $\frac{1}{6}$ of the total nitrogen. It would seem, therefore, advisable to employ this method in future, if it is desired to find the exact amount of effete nitrogenous matter eliminated by the kidneys.

TRAUMATIC RUPTURE OF LEFT COMMON FEMORAL ARTERY; LIGATURE OF THE TORN ENDS; RECOVERY (*British Medical Journal*, March 6).—A collier, while assisting to push some trucks up a steep incline, was violently exerting himself, when he heard a snap in the left groin. This was followed by pain and a small pulsating swelling. He, however, continued at his work some days, after which he consulted a surgeon, who treated him without relief. At the end of a month the swelling was about the size of two fists, but not growing. Getting no better, he was taken to the Manchester Royal Infirmary. On the way, the swelling suddenly increased, and became enormously distended, reaching, on admission, upwards beyond Poupart's ligament, and downwards nearly to the knee. The diagnosis of ruptured artery was made, and after the administration of chloroform and the application of an aortic tourniquet, an incision in the line of the femoral artery was made. Large clots were cleared out, and the ends of the torn artery were discovered at least an inch apart; these were secured by catgut ligatures. The vein was intact. The edges of the wound were brought together by metallic sutures, and the wound dressed with dry lint, and the limb wrapped up in a flannel bandage.

The patient made an uninterrupted recovery, and was discharged, cured, at the end of six weeks.

TRAUMATIC TETANUS SUCCESSFULLY TREATED BY CHLORAL HYDRATE AND BROMIDE OF POTASSIUM.—Dr. W. E. Pitman communicates to the *Virginia Medical Monthly* for March a case of a child five years of age, in whom violent tetanic spasms, clinched jaws, marked tendency to opisthotonos, with some dysphagia, came on suddenly (presumably as a result of some wound, although Dr. P. does not state this). Chloral hydrate, gr. v, with bromide of potassium, gr. xii, were administered every two hours, gradually lengthening the intervals, until spasmodic movements ceased. The child recovered.

EXCISION OF THE HEAD OF THE RIGHT HUMERUS FOR CARIES, THE RESULT OF AN INJURY.—Surgeon-Major J. H. Porter reports the following case (*Dublin Journal of Medical Sciences*, February): A soldier, aged 21, received, early in 1871, a blow from a broom-handle on the right shoulder, which caused him severe pain, and from which he frequently suffered afterwards. In July, 1873, he fell on the same shoulder, which was followed by severe inflammation in the part, with supuration and formation of an abscess in, or in the neighborhood of, the joint, which was opened in November.

When he arrived home from Bermuda, December 1, he was pale and emaciated, temperature 102°, pulse 105, and suffering from profuse night-sweats. The right shoulder was flattened, and presented the appearance of a dislocation of the head of the humerus, forward. There was a sinus at the inner edge of the biceps from which healthy pus was discharged. A probe could be passed through the sinus to the acromion process, but no bone could be felt. It was evident, however, that the head of the humerus was diseased and displaced. All interference with the arm caused intense pain in the shoulder.

On the 1st of January, 1874, excision of the head of the humerus was performed by a vertical incision of about five inches in length, extending from a point midway between the acromion and coracoid process, down the arm, parallel to the fibres of the deltoid muscle. The capsule of the joint and long head of the biceps were found to be extensively diseased, and the head of the bone in an advanced stage of caries. Two inches of bone were removed by butcher's saw. There was but little hemorrhage. The wound was dressed from the bottom with lint saturated with a weak solution of carbolic acid; a conical pad was placed in the axilla to prevent the end of the bone pressing inwards, and the fore-arm was carried across the body supported in a sling. As soon as the inflammation consequent upon the operation had subsided, passive motion was commenced by gently moving the elbow backwards and forwards for two or three minutes daily.

The progress of recovery was slow, and was retarded by the formation of numerous abscesses and an attack of phlegmonous erysipelas, during which a deep incision was made in the back of the arm. Through this opening the discharge of pus was encouraged, the first wound being closed, and after this he rapidly recovered. At present he can use a fork or spoon to assist in passing food to his mouth, can brush his hair, place his hand at the back or top of his head or on the opposite shoulder, and can carry the fore-arm across the back. He can also "present" a rifle from the right shoulder. During the course of the treatment the galvanic current was applied over the deltoid muscle, with much advantage.

HYDROCELE IN A FEMALE (*Southern Medical Record* for February).—Dr. G. A. Baxter was called to see a woman, married, 32 years of age, who gave the following history: Two years previously, while lifting a heavy bucket of coal, she felt a sharp pain in the inguinal region, but it passed away in a few moments. A few days afterwards she experienced some pain in the same region, extending into the labia majora, and accompanied by swelling. This continued some days longer, when, upon lying down one day, the swelling and pain suddenly disappeared almost completely.

The tumor continued in this condition for nearly two years, when, on some occasion having fallen over a chair, the labia majora was bruised, and the tumor began to increase in size, without, however, giving any

pain. On examination by Dr. B., a tumor was found as large as an egg, with its apex pointing to the external inguinal ring, and its base large and bulging out the upper portion of the labia majora. The tumor was at first supposed to be a hernia, then an abscess. Under the latter supposition, it was opened, when, instead of pus, serum alone came out. Speedy recovery followed.

HYDROPHOBIA.—Dr. J. G. Janeway, U.S.A., communicates to the *New York Medical Record*, March 13, an account of several cases of skunk-bites. The details of these are confirmatory of the views expressed by the Rev. H. C. Hevey in a recent number of the *American Journal of Science and Art*,—namely, that the malady produced by the mephitic virus is simply hydrophobia. Dr. J. gives notes of five cases of skunk-bites in which the period of incubation varied from twelve to twenty-one days, after which the characteristic symptoms set in and were rapidly followed by death. In one case of skunk-bite which did not terminate fatally, Dr. Janeway attributes the patient's recovery to the administration of heroic doses of strychnia, combined with free and repeated cauterization of the wound. Commencing with one-sixteenth of a grain of strychnia every three hours, the dose was gradually increased, and it was not until it had reached one-half grain, given every three hours for six days, that the characteristic effects of the drug became manifest.

ON THE DANGERS OF INTRA-RECTAL EXAMINATION.—Dr. R. F. Weir, in an article on this subject in the *New York Medical Record*, March 20, relates a case occurring under his care, recently, where manual exploration was made use of in a case of intestinal obstruction, with the view of ascertaining the appropriate point for the operation of artificial anus. The hand was inserted to the depth of eleven inches. The operation was then performed, but the patient died within twenty-four hours. Post-mortem examination showed a rent of the intestine extending from the level of the sacro-iliac synchondrosis to the bottom of the cul-de-sac of Douglass, and involving the muscular and peritoneal coats. No force was supposed to have been used, the hand having been introduced with the greatest care.

RADICAL CURE OF HYDROCELE BY ELECTRO-PUNCTURE.—Ehrhard (*Betz's Memorabilien*, Heft 8, 1874) has employed electro-puncture with permanent good effect in four cases of hydrocele. He uses the interrupted current from a small Gaiffe's apparatus. In three of the cases the hydrocele was only of short duration, and absorption took place in from three to four days, without any reaction. The hydroceles had not been previously tapped. In the fourth case the patient was a man aged 52, who had had hydrocele eight years and had been tapped many times. Under the use of electro-puncture, absorption of the fluid took place in three weeks. Four months afterwards, there was no indication of a return of the malady.

INTERESTING CASE OF NEUROSIS.—Dr. James Martin gives, in the *Dublin Medical Journal* for March, a short account of a young woman seized with sharp pain darting from the ensiform cartilage to the sixth and seventh dorsal vertebræ, accompanied by extreme weakness and discoloration of the skin over the sternum, the latter gradually extending over the body generally, but with white patches on the arms and elsewhere. Under the influence of tonics the pain and weakness disappeared, while the general discoloration, with the exception of the dark-brown patch over the sternum, which faded entirely away, remained persistent.

POISONING BY COKE FROM ITS USE FOR DOMESTIC PURPOSES.—Dr. R. Torrance (*British Medical Journal*, March 6) was called to see two servants who had been

making marmalade in the still-room of a gentleman's house, over a coke-fire. They had been attacked by giddiness, headache, and vomiting, accompanied in one case by weight in the head, ringing in the ears, strong tendency to sleep, and loss of muscular power. Removed to another room, the breathing was observed to be stertorous and difficult, and the action of the heart feeble. Stimulants, frictions, fresh air, and hot bottles to the feet soon brought about recovery.

MISCELLANY.

DE MORIBUS GERMANORUM.—We find in a recent book* the translation of a document which throws a singular light upon the moral condition of the Empire of Germany. This is a petition presented to the Reichstag, March 30, 1869, by the Central Committee of the German Evangelical Church, and referred to Bismarck. For the edification of our readers, we have copied some passages from it *literally*:

"There are very few of the streets of Berlin, even among those most frequented by the higher class, which are not infested by houses of prostitution. . . . In every quarter of the capital speculation has opened notorious markets to immorality. . . . The number of women placed under the surveillance of the police amounts to 71,319.† . . . In the course of last year (1868) the bodies of 154 infants were found in Berlin alone; . . . and these figures represent only a very slight proportion of the infanticides committed in the capital in the course of one year. . . . The number of illegitimate children in Berlin last year (1868) amounted to 150 in 1000 births. At Munich, during the same year, the births outside of marriage were in the proportion of 500 to 1000.

"In Magdeburg, there is not a street, perhaps not a house, which is not the asylum of lost women or of racouleuses. . . . In 1868, medical statistics ascertained 75,006 cases of syphilis for the entire city of Magdeburg (90,000 inhabitants). At Posen (50,000 inhabitants), without counting clandestine prostitutes, 1264 women were noticed by the police; that is to say, 1264 prostitutes and more among about 20,000 women, —16 per cent. In Stettin, among 85,000 inhabitants, of whom 20,000 were adult women, there were 2000 prostitutes,—i.e., 10 per cent.; and this not inclusive of concubines and kept women. The provisions of the Prussian penal code no longer suffice; the police is debauched, and prostitutes of both sexes walk brazenly abroad.

"At Breslau (156,000 inhabitants), 1088 prostitutes; the sum of the sentences of imprisonment pronounced last year against prostitutes amounts to 5750 weeks, or more than 110 years. Dantzic (60,000 inhabitants) has 850 women placed under the control of the police. At Memel (19,000 inhabitants) 254 names of prostitutes are

found upon the books of the police, an abstract of the number of public prostitutes. At Königsberg houses of debauchery are established in almost all the streets. In Cologne (114,000 inhabitants) there are 200 registered prostitutes; but it is known that about 1000 others ply the same trade. In Leipsic (78,000 inhabitants) there are fifty-two licensed houses. In the duchy of Anhalt the number of illegitimate births is 12 per cent., and 18 per cent. in the duchy of Dessau. The police have had to give up all measures of repression. At Bremen (70,000 inhabitants) there are to be counted but 72 girls placed under the control of the police, but the number there of public and clandestine prostitutes is incalculable. At Hamburg (215,000 inhabitants) there are 189 houses of prostitution and analogous establishments.

"Doubtless there are localities where the primitive purity of morals may be found, but they are rare, and immorality has invaded alike the small cities and least villages. In the country the disease augments each day, because legitimate unions have become almost the exception; for in each commune one-half the births are illegitimate."

To complete the picture of the griefs of the Evangelical committee, we will add the slightly comical reflections of the Berlin police:

"Immorality is such a 'common thing,' bare-faced licentiousness covers with so much freedom the members of German society with its ignoble *bavures*, and women, married or single, have reached such degradation, that an honest man trembles before marriage, and seriously asks himself whether the woman to whom he offers himself is not a residue of lubricity, and whether he is not exposed to admitting to his bed merely a mass of rottenness."—*Annual Report*, 1867.

Madame de Staël says that love, in Germany, is a religion, but a poetic religion. According to the foregoing figures, among one hundred women this religion numbers, then, about ten priestesses living at the altar. The priests are not counted!—*St. Louis Medical Journal*; from *Le Progrès Médical*, January 23, 1875.

"THE CENTENNIAL MEDICAL COMMISSION OF PHILADELPHIA" has now been fully organized, by the election of the following officers:—*President*, Samuel D. Gross, M.D., LL.D., D.C.L. Oxon.; *Vice-Presidents*, W. S. W. Ruschenberger, M.D., U.S.N., and Alfred Stillé, M.D.; *Secretary*, William B. Atkinson, M.D.; *American Corresponding Secretary*, Daniel G. Brinton, M.D.; *Foreign Corresponding Secretary*, Richard J. Dunglison, M.D.; *Treasurer*, Caspar Wister, M.D.; *Executive Committee*, Drs. Washington L. Atlee, D. Hayes Agnew, Robert Burns, David Burpee, J. S. Eshleman, Albert Fricke, N. L. Hatfield, H. Lenox Hodge, W. H. Pancoast, Robert E. Rogers, J. G. Stetler, L. Turnbull, and Edward Wallace, and the officers.

Arrangements have been made to hold an International Medical Congress early in September, 1876, in Philadelphia, at which discourses will be read upon Medicine and Medical Progress in the United States, on Surgery, Obstetrics, Chemistry and Pharmacy, Ma-

* Les Odeurs de Berlin, Leouzon le Duc.

† Berlin has about 700,000 inhabitants: the number of adult women would be, therefore, in the neighborhood of 170,000. The proportion is beautiful!

teria Medica, Medical Jurisprudence and Toxicology, Hygiene and Social Science, Medical Biography, Medical Education and Institutions, and Medical Literature. The morning sessions will be devoted to general business and reading these discourses, while the afternoon sessions will be devoted to sections on Medicine, on Surgery and Anatomy, on Obstetrics, on Chemistry, Materia Medica, Hygiene, and Medical Jurisprudence, and on Ophthalmology and Otology. This congress will consist of delegates, native and foreign, representing the American Medical Association, the various State medical societies, and the medical societies of Europe, Mexico, the British Dominions, Central and South America, the Sandwich Islands, the East and West Indies, China, and Japan. The congress is to be organized by the election of a president, thirteen vice-presidents, seven of whom shall be natives and six foreigners; a recording secretary, two corresponding secretaries, a treasurer, an executive committee, and a committee on publication. It has been agreed that no vote shall be taken during the sittings of the congress upon any topic discussed or address delivered. The preparation of these discourses has been intrusted to able hands, and it is intended to publish them in an appropriate volume commemorative of the occasion.

Not long since, *L'Union Médicale* directed the attention of its readers to the statement of Dr. Simmons as to the happy results, in cases of obstinate vomiting, of the administration by the rectum of chloral hydrate. Dr. Simmons recommended to begin with a dose of thirty grains morning and evening. By mistake, it was printed in *L'Union Médicale* thirty grammes,—an enormous difference. A subscriber not long after came to grief by administering per rectum half the quantity, fifteen grammes, to a hysterical patient.

A few minutes after the administration of the chloral the patient became completely collapsed, and remained in a state of unconsciousness, with constant tendency to syncope, for several hours. She was restored to consciousness with great difficulty by the persistent efforts of her physician.

Very naturally, the subscriber calls the attention of *L'Union Médicale* to its error. That journal replies that for a long time the *grain* has not been employed in French prescriptions, and by a misprint *gramme* was substituted for *grain*. It thinks the excessive dose thus recommended should have made readers cautious as to its exhibition.—*Boston Medical and Surgical Journal*.

NEW DISEASE IN BALLET-GIRLS.—At a meeting of the Society of Physicians in Vienna, reported in the *Wiener Medizinische Presse*, Dr. Schulz described a new form of disease which hitherto he had observed only in ballet-girls, and which manifested itself in a cramp of the muscles of the calf of the leg. It occurred chiefly among those who were in the habit of performing a *pas seul* on the points of the toes. The disease appeared to be similar in its character to writer's palsy. The muscle which is the chief agent in supporting the body upon the points of the toes is the flexor longus

pollicis. This position, which is accompanied by a rigidity of the whole limb, can only be maintained when the foot is supported by a shoe made for this particular purpose. This muscular cramp was relieved in all cases by faradization. Professor Patruban, in reply to this communication, stated that in his opinion it was "anatomically, physiologically, physically, and artistically" impossible that a dancer should stand upon the points of the toes; but that the sesamoid bone was the point of support. In proof of this view he referred to Hyrtl's lectures, and to the fact that Dr. Schulz had never had an opportunity to see the naked foot in this position.—*Boston Medical and Surgical Journal*.

THE NEW HÔTEL-DIEU.—According to *L'Union Médicale*, the changes in the original plan for the new Hôtel-Dieu are rapidly being carried out. They consist especially in lowering the roofs, whose excessive height cut off the air and sunlight from the courts and promenades intended for convalescents, and in the removal of one story from the two wings which front on the Quai Napoléon. And there is reason to hope that the inauguration of this new structure, certainly one of the most beautiful in Paris, will take place in the not distant future.—*Boston Medical and Surgical Journal*.

AMERICAN MEDICAL ASSOCIATION.—The Twenty-sixth Annual Session will be held in the city of Louisville, Kentucky, on Tuesday, May 4, 1875, at 11 A.M.

Tickets will be issued to delegates from Philadelphia to Louisville and return, for \$24, on presenting an order from the undersigned. Those who want orders should send a stamp and say which route they prefer, Pennsylvania Central, or Philadelphia, Wilmington & Baltimore.

WM. B. ATKINSON, 1400 Pine Street,
Permanent Secretary.

NOTES AND QUERIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

THE next conversational meeting will be held Wednesday, April 28, at 8 o'clock P.M., at the hall of the College of Physicians.

Obituary notices of the following deceased members will be read: Drs. John Bell, M. M. Levis, L. S. Bolles, W. A. Hoffman, B. Price.

The medical profession in the city are cordially invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM APRIL 13, 1875, TO APRIL 19, 1875, INCLUSIVE.

EDWARDS, E. A., SURGEON.—Granted leave of absence for one month on Surgeon's Certificate of Disability. S. O. 71, Military Division of the Atlantic, April 14, 1875.

MOORE, JOHN, SURGEON.—Assigned to duty as Medical Director of the Department. G. O. 5, Department of Texas, April 13, 1875.

JAQUETT, G. P., ASSISTANT-SURGEON.—Assigned to temporary duty with Geologists' escort to the Black Hills. S. O. 44, Department of the Platte, April 13, 1875.

HOFF, J. V. R., ASSISTANT-SURGEON.—Assigned to temporary duty at Fort Sanders, Wyoming Territory, during temporary absence of Dr. Jaquett. S. O. 44, c. s., Department of the Platte.

SATURDAY, MAY 1, 1875.

ORIGINAL COMMUNICATIONS.

REPORT OF A COMMITTEE APPOINTED BY THE PATHOLOGICAL SOCIETY OF PHILADELPHIA TO EXAMINE THE SPECIMEN OF IMPERFECT-CYCLOPS MONSTER PRESENTED BY DR. F. H. GROSS.

Read March 11, 1875.

YOUR Committee beg leave to report that upon examination they found that the specimen was an example of the deformation known as the *ethmocephale* of Saint-Hilaire, the exact position of the specimen being, it was thought, in close connection with the cyclops group of monsters.

The body was that of a male child at full term. It presented nothing unusual apart from the head and face, to which your Committee's remarks will be confined.

FIG. 1.

VIEW OF THE HEAD, BEFORE DISSECTION.

The forehead was much contracted from side to side, and presented a single frontal protuberance. The palpebral fissures were approximated, each fissure measuring five lines in length, and directed slightly downwards and outwards. The space between the eyes was nine lines in width, and was occupied by the base of the nose. The latter organ was the most remarkable feature of the specimen. It consisted of a tubular proboscis-like organ, which measured eleven lines in length along its upper surface, five lines in length along its lower, nine lines in width at the base, and five and a half at the tip. It was flexible, covered throughout with integument, presented a single sub-rounded nostril, having somewhat tumid margins, which, towards the middle, both above and below, slightly projected. The

interior of this organ appeared to be a *cul-de-sac*, without communication with the mucous membrane.

The lips were well formed, the oral fissure measuring ten lines in length. The upper margin of the fibres of the orbicularis oris muscle was defined by a well-marked wrinkle. The space between this and the base of the nose was smooth, measured nine lines in height, and was continuous with the cheek-surfaces.

Upon removing the calvaria, it was found that the brain-case was not entirely occupied with the brain, the top of the cerebral hemispheres failing to reach the sagittal suture by one inch. Its appearance was, moreover, remarkable by the failure of the posterior cerebral lobes to overlie the cerebellum. The sides of the longitudinal fissure at its posterior part were widely divergent, disclosing the *velum*. The space not occupied by the brain was filled with a thin serous fluid. The dura mater sent no folds between the encephalic masses; so that the great falx and tentorium were absent. There was, of course, no longitudinal sinus.

When the brain was removed, the dura mater was seen lining the base of the skull in the usual manner, so far as the posterior and middle cerebral fossæ were concerned. That lining the anterior cerebral fossa presented a smooth surface, not interrupted by any eminence which would indicate the position of the *crista galli*. The transverse diameter of the anterior cerebral fossa was one inch and ten lines. There was no appearance of olfactory grooves or cribriform plate.

FIG. 2.

THE BRAIN VIEWED FROM ABOVE.

a, the cerebellum; *b*, corpora quadrigemina; *c*, probable position of the optic thalamus; *d*, the median sulcus; *e*, the occipital lobe; *f*, the first posterior transverse convolution; *g*, the first anterior transverse convolution; *h*, the parieto-occipital fissure.

Viewed from above (Fig. 2), the encephalon presented the following appearances: The cerebellum (*a*), corpora quadrigemina (*b*), and optic thalamus (*c*) were exposed; the cerebrum terminating four lines in advance of the cerebellum. The cerebrum was imperfectly divided into two hemispheres. The longitudinal fissure was represented by a median

sulcus (*d*) measuring nine lines in length, which did not extend downwards to a corpus callosum, —this commissure being entirely absent; nor did this sulcus differ in any respect from those elsewhere seen on the cortex. The occipital lobes (*e*) were not approximated; indeed, it was by their want of approximation that the optic thalami and corpora quadrigemina were seen.

FIG. 3.

THE BRAIN VIEWED FROM BELOW.

a, medulla oblongata; *b*, pons Varolii; *c*, infundibulum; *d*, inferior median sulcus; *e*, fissure of Sylvius.

Viewed from beneath (Fig. 3), the encephalon presented a normal medulla oblongata and pons. There were no mammillary bodies. The under part of the mass, answering to the conjoined thalami, (?) presented a conspicuous infundibulum (*c*). The posterior perforated space was absent; the two anterior were conjoined into a central space placed in advance of the infundibulum. In front of the latter space was a median sulcus, measuring seven lines in length. The olfactory nerves were absent. The position of the optic tract was obscurely defined. No trace of a chiasm was seen.

The general aspect of the cerebrum led your Committee to determine the significance of its malformation to be as follows: that at an early period in the history of the foetus, at a time when the hemispheres were about to be discerned, the development of the mass was arrested. A decided attempt at a symmetrical division of its parts was announced, which, however, was not successfully attained in many parts of the cerebrum: thus a right and a left hemisphere were recognized, united by two conspicuous transverse convolutions in front, and by two shorter and less conspicuous convolutions behind. The superior median sulcus was terminated posteriorly by the first posterior transverse convolution. The first anterior transverse convolution presented upon its upper margin a pyramidal offset, which abruptly arose, and was lodged within the superior sulcus, bifurcating it in front.

In the right cerebral hemisphere the fissure of Sylvius began about a line above the level of the anterior perforated space, and ascended less than half the way up the side of the hemisphere. In

front of this fissure were the transverse convolutions, the fissure joining the sulcus between them. Behind it was a large smooth surface which answered pretty

FIG. 4.

PROFILE VIEW OF THE BRAIN SEEN FROM THE RIGHT.

a, anterior superior transverse convolution; *b*, superior median sulcus; *c*, the posterior superior transverse convolution; *d*, the parieto-occipital sulcus; *e*, the occipital lobe.

nearly to the posterior half of the hemisphere. The fissure of Rolando began at the anterior border of the superior median sulcus, with which it was continuous, and extended downwards and outwards to the end of the first anterior transverse convolution. The position of the parieto-occipital sulcus was marked by a wide fissure, bounded in front by the posterior superior transverse convolution, and behind by the occipital lobe.

FIG. 5.

PROFILE VIEW OF THE BRAIN SEEN FROM THE LEFT.

a, parieto-occipital sulcus.

The left cerebral hemisphere presented a fissure of Sylvius which began at the level of the anterior perforated space, and did not ascend the side of the hemisphere, but was deflected forwards and inwards, to be continuous with the sulcus between the two anterior transverse convolutions.

The fissure of Rolando passed outwards and backwards, not parallel with the median sulcus, but outwards along the side of the hemisphere to the first anterior transverse convolution. The parieto-occipital sulcus was less deep than that on the right side, but wider. About the posterior third of the hemisphere, below, and at its sides, no convolutions were seen.

These features represented, it was thought by your Committee, the most important points of the superficies. Of minor value would appear to be the presence of a conspicuous sulcus upon the upper surface of either hemisphere, which on the right side joined the fissure of Rolando in front and at its termination, and extended backwards and nearly parallel to the median sulcus, to terminate in the occipital lobe by a Y-shaped flange. A similar sulcus on the left side had no connection with the fissure of Rolando anteriorly, but extended back-

wards and outwards to terminate in a similar manner with that of the right side.

Two other sulci were seen, which were not symmetrical: the one on the right was a little depression about the middle of the side of the hemisphere; the one on the left, somewhat larger, seen upon the upper portion of the occipital lobe.

It will be observed that all the parts are better developed upon the left than upon the right side.

The interior of the cerebrum was a simple cavity, without any attempt apparent at the formation of *fornix*, *corpus callosum*, or *septum lucidum*. No prolongations were seen in the position of the olfactory nerves. Posteriorly, the cavity was continuous, with a cul-de-sac about seven lines in depth, apparently formed by the doubling of the cerebral tissue at that point; and the fold thereby made determined the posterior inferior border of the hemisphere. This cul-de-sac your Committee took to be in the position of the future middle horn of the lateral ventricle.

A longitudinal section of the skull was made a little to the right of the median line; yet so narrow was the pre-sphenoidal portion of the body of the sphenoid bone that the section was directed through the right optic foramen, where an optic nerve was found in position.

FIG. 6.

PROFILE VIEW OF THE IMPERFECT INTER-ORBITAL SEPTUM SEEN FROM THE LEFT.

a, the frontal bone; *b*, the ethmoid bone; *c*, the lachrymal bone; *d*, the superior maxilla.

An osseous column was now displayed, which extended in the median line from the frontal bone to the intermaxillary bone, and which was thought to answer to the associated ethmoid and lachrymal bones. No trace of the vomer could be found. The above mass measured six lines in height, six from behind forwards, and three in width. It formed an imperfect septum between the orbits, which served to separate these cavities anteriorly only, while posteriorly the eyeballs were surrounded by a common mass of fatty tissue and muscle.

The section exposed the dental sacs. The left half contained almost the whole of the palate, presenting anteriorly an intermaxillary bone, the outline of which was well marked on the upper or orbital surface. This surface terminated in an ante-

rior nasal spine. This latter process was much more pronounced than is normal, or rather the intermaxilla was deeper than normal, by which the process in question was raised above the level of the orbits. The outer walls of the orbits were normal. The floor was common to both, and was formed by a coalescence of the orbital plates of the superior maxillæ with the intermaxillæ. The infra-orbital canals were in position.

The hard palate terminated posteriorly in a normal velum. There was no room for the posterior nares: in fact, in their place was found a mere pouch of mucous membrane between the two pterygoid processes, extending below into the velum and above into the roof of the pharynx. The Eustachian tubes were in position. At the line of junction of the nasal columns with the frontal bone (Fig. 6, *a*) there was on either side a foramen transmitting a nerve which was traceable into the cranial cavity. Your Committee would take this nerve to be the nasal branch of the ophthalmic. This fact alone led them to conclude that the upper portion of the septum consisted of the ethmoid bone (*b*). The latter structure presented in the median line an imperfectly developed vertical plate, and on either side, appearing respectively in the right and left orbits, was an irregular mass of bone, which represented the lateral mass. This articulated above with the frontal bone, and below with the lachrymal (*c*) of its own side. Each lateral mass inclined towards its fellow, so that the two touched behind their entire length, forming the posterior free edge of the upper half of the column. The plates were also approximated in front, at their upper portions, but were slightly divergent below, to define, with the aid of the lachrymals, an opening which answered in position to the nasal chambers, within which was seen the lumpish perpendicular plate. The lower bone of the septum on either side was undoubtedly the lachrymal. It presented on its outer surface a marked groove which was completed by the ascending portion of the intermaxillæ. On the left side the groove was better marked, the posterior inferior angle of the bone being prolonged into a hook-like process which was attached by ligamentous union to the upper surface of the intermaxillæ. The anterior inferior angle of the bone was attached to the nasal spine of the intermaxillæ. The lachrymal bones converged and touched behind, to form a sharpened edge, which constituted about the lower half of the posterior border of the nasal column. Anteriorly, the bones aid in defining the lower portion of the lateral walls of the nasal chamber. The integument lining the proboscis-like organ was evidently continuous with the true skin-surface, but had united with the parts above described so far as to have entered and been held in close connection with the interior of the rudiment of the nasal chambers.

The thoracic and abdominal viscera were normal. A section of the lungs floated in water.

A CASE OF ATRESIA VAGINÆ.

BY H. S. SCHELL, M.D.

Read before the Pathological Society of Philadelphia.

ON the 2d instant an Irishwoman named Mary G. was admitted to St. Mary's Hospital, on account of a painful tumor of the abdomen. She was 30 years of age, and had been married five years. The hypogastric region was filled with a round body about the size of the womb in the fourth month of pregnancy.

From this mass an oblong tumor, about six inches long by two and a half inches broad, extended obliquely into the left lumbar region, and was movable from side to side to the extent of a couple of inches. Both of these bodies were rather hard, tense, and elastic. The patient stated that she had never menstruated, but that she had suffered from abdominal pains at monthly periods for the last twelve years. She had noticed the tumor for the last five years only. She was now scarcely ever entirely free from pain, and she anticipated the monthly exacerbation in a few days after her admission. On attempting to make a per vaginam examination, it was found that the canal was apparently somewhat in front of its usual position. It grasped the forefinger closely, and curved round immediately behind the os pubis. It was dilated at its upper part about the tip of the finger, but no os uteri could be felt.

The tumor was encountered at two and three-quarters inches from the external orifice. The rectum was large and flaccid. It dilated, immediately after passing the sphincter, into a sort of pouch. Its anterior wall was in contact with the perineum, the apparent vagina, and the base of the tumor, and, finally turning off to the left, was lost to the touch.

Visual inspection of the external organs of generation revealed well-formed labia, nymphæ, and clitoris. No normal urethra could be found, but when the finger was withdrawn from the anterior canal it was followed by a few drops of urine. The perineum was unmarked even by a dimple. When a finger was introduced into the anterior canal, and another into the rectum, there was evidently only the thickness of the walls of the two passages between them. No fibrous cord could be detected, and the coats of the two canals could be made to glide upon each other to some extent.

It seemed to me probable that this was a case of absentia vaginæ; that the large tumor consisted of the uterus distended with retained menses, and that the movable offshoot might be a Fallopian tube enlarged from the same cause.

On the 7th instant, at the probable monthly period, the woman suffered such extreme pain in the tumor that it was found necessary to resort to the hypodermic use of morphia to render her condition tolerable. As she was exceedingly anxious to be relieved, I proposed to make a vagina by incision in the perineum and careful dissection of the urethro-rectal septum, and to let out the retained menses.

On the 14th, a week after the monthly period, in consultation with Drs. Keen and Mears, it was decided to etherize the patient, and make, if pos-

sible, a more thorough examination before operating. The woman proved to be very refractory to the influence of the ether, and the consumption of a pound only produced incomplete anæsthesia, during which she made violent expulsive efforts. In one of these, a large portion of the tumor, about the size of a child's half-born head, was forced for a moment through the anus.

During the examination, the length, large size, and natural appearance of the anterior canal produced some doubts as to the correctness of the previous diagnosis. It was thought that it might be a common duct for the bladder and uterus. To this uncertainty was added the fact that the proposed operation was of a delicate character, and a fatal result from it not impossible. Under the circumstances it was decided to use the aspirator,—1, to ascertain the nature of the contents of the tumor; and 2, if found to be menstrual fluid, to relieve the uterus of most of it; and to make the proposed dissection at some future day, if thought desirable.

The puncture by the aspirator was accomplished through the rectum by means of the smallest needle, and two or three drachms of thick, slimy, red fluid removed.

It was then found that the joint between the needle and the rubber tube was not quite air-tight, so that the fluid could only be withdrawn slowly and with great difficulty. The needle was therefore removed from the tumor, with the intention of having the instrument made perfect and of taking away the rest of the fluid in a few days. The next morning, however, found the patient laboring under a violent attack of general peritonitis, which resulted fatally, in spite of treatment, on the evening of the 16th.

A post-mortem examination, made the following day, showed that the peritonitis had been caused by the diffusion throughout the abdominal cavity of the menstrual fluid previously contained in the tumor. What remained of the hypogastric tumor was now a flaccid, nearly empty sac, capable of holding about a quart. It proved to be the occluded and distended vagina. Its walls were one-fourth of an inch in thickness, except in the Douglas's cul-de-sac, where for a couple of square inches they were thin as paper. In the lower part of this attenuated region the fatal rupture had taken place, the rent being only large enough to admit an ordinary probe.

The body in the left lumbar region was found to be the hypertrophied and elongated uterus. It measured five inches long by two and a quarter inches broad. Its interior was divided into two unequal cavities, of which that of the neck was perhaps treble the capacity of the body. The walls of the organ varied in thickness from three-fourths of an inch in the body to half an inch in the cervix. The cavity contained about a fluidounce of menses, and communicated with the vaginal pouch by an orifice similar to that of the virgin uterus.

The right Fallopian tube was normal in its origin, and its distal extremity was dilated so as to hold an ounce or two of fluid.

The left tube had an irregular origin near the internal os uteri. The apparent vagina proved to

be the urethra. It was three and a half inches long, its walls thick and muscular, and it led to the bladder only. The walls of the latter were thickened and its mucous membrane congested. The fluid removed by the aspirator and also that taken post-mortem from the uterine and vaginal cavities showed under the microscope a large quantity of granular detritus, some mucus- and blood-corpuscles, and numerous crystals of cholesterolin.

It was impossible to find in the rectum or vaginal pouch any trace of the passage of the aspirator-needle.

b, rectum; *c*, uterus; *d*, cervix uteri; *e*, vaginal sac; *f*, bladder; *g*, urethra; *a*, point of rupture of vaginal sac.

In the accompanying drawing I have endeavored to represent as accurately as possible a sectional view of the condition of the parts previous to the rupture of the tumor. An examination of this diagram suggests the theory that at the age of puberty the vaginal pouch was probably not far from the perineum; but as the menstrual fluid accumulated the sac gradually rose from the pelvis into the abdomen, dragging with it the rectum and urethra, the latter becoming elongated and hypertrophied to accommodate itself to the new relations of the parts, and its capacity being enlarged perhaps by *intromissio penis*.

The rectal dilatation is not so readily accounted for, but it is possible that it may have officiated vicariously in the performance of marital rites.

It is difficult to determine in this case precisely when the rupture of the vaginal sac took place; whether it was produced by the pressure used in making the examination by the puncture of the needle, or by the expulsive efforts of the woman herself. The possibility of such an occurrence was contemplated before the examination was made, and much care was taken in manipulating the parts, so that it seems improbable that this could have caused the trouble.

As to the implication of the needle in the disaster, my object was to make the puncture anterior to Douglas's cul-de-sac, so as to avoid the peritoneum if possible; and I think I succeeded. I am therefore disposed to attribute the accident to the

patient's bearing-down efforts, which were mostly reflex in their character, and caused by the introduction of a foreign body—viz., the finger or sound—into the congested and irritable bladder.

This view is rendered more probable by the fact that when the puncture was made, about five minutes after the most violent effort, the impression produced upon my mind was that the tumor was softer and farther away from the perineum than it had ever been before. At all events, in consequence of the excessive thinning of the posterior vaginal wall, a rupture at that point was imminent at any time.

The case is instructive as displaying in an unusual manner the peculiar danger of this malformation, and teaches a valuable lesson as to the propriety of an early operation.

PHILADELPHIA, February 27, 1875.

The specimen was referred for examination to the Committee on Morbid Growths, which reported, March 25, as follows:

"In Dr. Schell's specimen of congenital occlusion of the vagina, your Committee have found the black coloration of the walls of the pouch due to presence of hæmatoidin crystals and pigment-granules in the submucous and connective-tissue layers of the dilated vaginal canal. This coloring-matter has unquestionably been absorbed from the retained menstrual blood.

"The walls of the uterus are slightly thickened; there is, however, no dilatation of the uterine cavity proper, simply a funnel-shaped distention of its cervical canal. The absence in this specimen of hæmatometra, so generally an attendant upon congenital atresia of the genital canal after the establishment of menstruation, seems to your Committee explicable upon the fact that in this case the ante-flexion of the uterus, with the ensuing kinking of the organ at the internal os, has acted as a mechanical hindrance to its further distention.

"The manner in which the uterine cavity has been laid open prevents us from ascertaining whether a complete stenosis existed at the internal os. The urethra very readily admits the insertion of a finger."

NOTES OF HOSPITAL PRACTICE.

PHILADELPHIA HOSPITAL.

A CASE OF DOUBLE MONSTER.

Reported by Dr. E. E. MONTGOMERY.

M. K., æt. 20, a strong, healthy German girl, unmarried, went into labor at full term on the morning of April 5, 1875. The first part of her labor was characterized by feeble, irregular pains. I was called to see her at nine o'clock in the evening. At this time the os was dilated to the size of a common half-dollar, the membranes had ruptured, and the head, covered by the womb, was presenting at the inferior strait. An anodyne was administered, after which the patient remained comparatively quiet until nine of the next evening; at this time the pains became more frequent. Upon examination, I found the os well dilated and the vertex presenting in the first position.

Although from this time the pains were powerful, the

progress of the labor was slow. Shortly after ten, the child's head emerged from the vulva, and labor again stopped. Drs. Edwards and Deaver attempted to stimulate contractions by making gentle pressure over the uterus, while I delivered the shoulders. After the delivery of the shoulders and the upper part of the body of the child, it made no progress, though the pains were severe and I made considerable traction upon the child. Finally passing my finger along its back until I reached the buttock, I in this way succeeded in delivering the lower extremities. The body of the child was held closely to the vulva by the umbilicus. We supposed we were dealing with a case of short cord, and were further confirmed in this belief by seeing a mass lying in the vulva which looked like a portion of the placenta. After waiting a few minutes, endeavoring to resuscitate the child, I introduced my hand to bring away the placenta, and came in contact with the foot of another child. This second child was rapidly delivered with its back to the pubes. The after-birth came away within ten minutes.

Neither child showed any signs of life. The head of the second was pretty well crushed by the contractions of the uterus.

The children, both males, together weighed ten pounds and four ounces, and were connected at the umbilici by a band three inches in length. Near the bodies this band was constricted, but at the centre it was seven inches in circumference, and contained a portion of the intestines. At each side the band was covered with integument to the distance of an inch, while at the under portion the integument extended across. Neither child had a perforate anus. The genitalia were well developed, as were the lower extremities, excepting a contraction of the muscles of the right leg of the first child, turning the heel in and the bottom of the foot upward.

The placenta was large, but presented no separation; the cord, which consisted of two arteries and two veins, came off from its centre. The membranes of the first child covered the whole foetal surface of the placenta, while those of the second arose from the placental end and surface of the cord, and consequently were enveloped by those of the first. The membranes of the second child were apparently a reflexion of those of the first, thus placing the child without, instead of within, the membranes.

Upon inquiry, the mother says that when she was four or five months pregnant she fell, and, as a result of the injury, her menses returned, and continued regularly until her delivery.

Assisted by Dr. Edwards, I made sufficient dissection, without destroying the band, to demonstrate the circulation and the connection between them. The umbilical cord, three inches from the children, bifurcated, and, entering the band, had a portion directed towards each child.

The circulation in the two children is the same. The vein entering the umbilicus takes its usual course to the liver; the abdominal aorta gives off but one hypogastric artery, which, passing out at the umbilicus, becomes the umbilical artery. The peritoneal surface of one was continuous with that of the other through the umbilical openings. The greater portion of the small intestines was in the abdominal cavities, but the ilei pass through the umbilical openings to the common sac, where they join to form a triangular reservoir or receptaculum an inch and a half in length by an inch in breadth at the base, which is continued by small intestines to the cæcum.

This union is some three inches from the cæcum. The latter has two appendices well developed, one on each side of a layer of peritoneum. The common large intestine terminates at the lower portion of the band in

a large pouch, which opens by a small slit-like aperture into a sulcus. This sulcus, beneath the peritoneal surface, extends from the body of one child into that of the other.

As the external genitalia were well developed, we supposed the urinary apparatus perfect, but found the urethrae closed within one-fourth of an inch of the meati, and no indication of the development of a bladder in either. On raising the ureters and introducing a probe, we found it to emerge from the sulcus at either side of the anus.

ALLGEMEINES KRANKENHAUS, VIENNA.

SERVICE OF PROF. CARL BRAUN, MARCH 23, 1875.

TWO CASES OF DUPLEX UTERUS—PREGNANCY—RETAINED MENSTRUATION—DEATH—POST-MORTEM.

ON the morning of November 27, 1874, a patient, about 26 years of age, primipara, was admitted to the obstetrical department of the Allgemeines Krankenhaus, and, having had for some hours labor-pains, was transferred to the ward assigned to patients in labor. She was at once taken charge of by a student, who proceeded, according to the usual method adopted here, to ascertain the position of the child by palpation and auscultation. The irregular outline presented by the abdomen, however, deceived him, and he diagnosed a transverse position.

As Professor Braun made his morning visit, his attention was called to the case, and he at once proceeded to make an examination.

Inspection revealed a large tumor on the right side, running up from the symphysis and Poupart's ligament in an oblique direction, and having its base to the right of the umbilicus. This tumor had, in form and extent, the appearance of a pregnant uterus at full term. Its right and upper borders could be distinctly felt and outlined, while it was movable in the peritoneal cavity. Palpation revealed the presence of a body within the tumor, and, on auscultation, the foetal heart-sounds were readily perceptible. The left border of this tumor, at a point three inches below the umbilicus, was found to merge in another of about one-half its size. Examination showed it also to have an origin in the median line, while its fundus lay to the left of and a little beneath the umbilicus. It was very elastic to the touch. The body and fundus were quite movable, and it might have been pronounced, by an inexperienced diagnostician, an ovarian tumor having an attachment to the uterus on its left border. Attention to this tumor during the occurrence of labor-pains showed it then to be much harder and more resisting than between the periods of uterine contraction, so that there was a resemblance, not only in form, but apparently in function, between the tumors on the right and left sides of the abdomen.

On vaginal examination, a septum was found in the cervix running antero-posteriorly, and the case was diagnosed as one of duplex uterus. All attempts to discover any body in the left horn were fruitless.

The case was then left under close observation for four hours, and, at the expiration of that time, brought into the clinic. Inspection and palpation then showed no special change to have taken place. The amniotic fluid had not yet escaped, but labor-pains had become more frequent and stronger. The contraction of the right horn of the uterus was still invariably found to be attended by a contraction of its fellow on the left. Vaginal examination was repeated, and the head having descended, the position being L. O. A., it was found to be impossible to detect more than a single cavity in the cervix. The septum previously detected had either been ruptured, or the contraction of the right horn of

the uterus had so altered the relations of the parts, by forcing the head downward, that the left cervical canal was obliterated and driven backward and upward out of reach.

Professor Braun did not consider the case as demanding any assistance, and the patient was transferred to the ward.

Some time afterwards, a change in the form of the abdomen was observed, and on examination it was found that the child had been driven through the ruptured septum into the left uterine horn. In a short time delivery was accomplished: child still-born. The patient seemed exhausted, and fears were entertained that pyæmic symptoms might manifest themselves, on account of the large surface of lacerated tissue due to the rupturing of the uterine septum. On the day following, a rise in temperature and pulse indicated the correctness of this view. Her condition continued very critical for two weeks, when an attack of pleuro-pneumonia complicated it, and the patient died on the 19th of December, twenty-two days after delivery.

The post-mortem examination showed that subinvolution had but very imperfectly progressed, the right

FIG. 1.

horn (*a*), the seat of impregnation, being about as large as a child's head at the seventh month of utero-gestation, while the left was twice as large as the normal uterus. The uterine tissues were infiltrated with pus, which was also found in the uterine veins and Fallopian tubes. Traces of the ruptured septum (*c*) were distinctly observable, extending from the os externum to a point marking the junction of the right and left horns.

In a case of duplex uterus previously occurring here, the left horn, non-impregnated, being caught under the projecting promontory of the sacrum, impeded the course of labor. By steady and persistent pressure it was forced upward, and delivery was accomplished without further difficulty.

The second case was that of a young woman who presented herself at the clinic of Professor Braun, January 21. She complained of having been frequently troubled with dull aching pains in the pelvis; but her appearance, far from indicating any severe or protracted suffering, was that of a person enjoying the best of health. The pains she spoke of were more severe at the menstrual epoch, and sometimes almost insupportable. The menses were regular in their occurrence, moderate in quantity, and lasted the usual time. They had first appeared about two years before, and until then she had never experienced any difficulty. With each recurrence of the same, however, the pain increased in intensity, and she was very desirous that something should be done to alleviate her suffering.

External examination proved the presence of a tumor situated just below the pelvic brim, on the left side. It was round, hard, and inelastic to the touch, and about three inches in diameter. Vaginal examination also revealed the same tense resisting body, without fluctua-

tion, descending below the vaginal extremity of the cervix, and involving it. The uterus was thrust away from the median line to the right. The sound was introduced two and one-half inches, gliding off to the right on entering the cervix in the direction of the fundus uteri.

Upon considering the history of the case, the symptoms, and the results of the examination, Professor Braun stated it to be his opinion that the case was one of intra-mural fibroid involving the left wall of the uterus and also that of the cervix.

The patient insisting upon some operation for relief, it was decided to proceed to operative measures at once. The operation by enucleation was considered most advisable, and, as a large portion of the tumor descended into the left upper portion of the vagina, no special difficulty was anticipated. An incision through the cervical surface of the tumor was determined upon, its enucleation, as far as possible, by the hand, aided by instruments if necessary, and subsequent extraction by means of the craniotomy forceps.

The incision, about one and a half inches in length, was made in the tumor, when, to the surprise of all present, a dark, bloody, tenacious fluid poured forth from the opening. Professor Braun, at once convinced of the nature of the tumor by the appearance of the fluid, immediately pronounced the case to be one of duplex uterus, with congenital atresia of the external os on the left side and consequent damming up of the menstrual secretions. The tumor, which had presented the physical signs of a fibroid, was the very greatly distended left cervix, its walls being also much hypertrophied. The left horn of the uterus was thrust downward and backward into the pelvis, and had escaped the observations which had been made per vaginam.

The patient was carefully removed to bed, and every attention bestowed which it was thought would avert any serious result; but despite all treatment the temperature rapidly rose on the day following, other symptoms of peritonitis set in, and she died on the 25th, four days after the operation. The peritonitis was due possibly (may it not be said probably?) to blood forced into the peritoneal cavity through the left Fallopian tube.

On post-mortem examination, the right horn of the

FIG. 2.

uterus was found of normal size and healthy, the left considerably larger than the right, but its tissue also healthy; the cervix of the latter (*b*) nearly spherical in form and exceedingly dilated, being, as already mentioned, about three inches in diameter. Through the incision (*a*) which had been made in the operation, it opened into the cervix of the right side. The left Fallo-

pian tube (*c*) was long and greatly distended, being nearly two inches in diameter, and filled with a brownish, bloody fluid, adherent to its walls and similar to if not identical in character with that which exuded from the cervix when pierced. The ovaries were large, and the right one exceedingly interesting on account of the remarkable development of the Graafian follicles.

Professor Braun stated that during an experience of thirty years, during which more than one hundred thousand patients had been under his care in the hospital wards, and a large number had been treated by him in private practice, he had never before met with a case of congenital atresia of the *external os uteri*. A few such cases are reported in the literature of gynaecology.

G. WILDS LINN.

TRANSLATIONS.

THE NERVI VASORUM OF THE ARM.—In Reichert and Dubois-Reymond's *Archiv* for February, 1875, Hermann Frey (Medical Student) communicates the results of his study of the gross anatomy of the nervi vasorum of the upper extremity. After careful dissection of a number of subjects with this end in view, he feels warranted in making this contribution to an almost entirely neglected point in anatomy.

Like the larger nerve-trunks, the nervi vasorum run as directly as possible to their destination; in their course deriving support and protection from their proximity to the strong sensor and motor nerves, which invariably accompany the arteries and generally the veins. The rule that an artery is supplied by its accompanying nerve does not, however, limit its nervous supply to one source, but it may be innervated in different portions of its course by different nerves. Nor is a vessel necessarily supplied by its largest accompanying nerve: it may depend wholly or in part upon some smaller branch; thus, the first collateral branch of the ulnar is innervated by the ulnar collateral branch of the radial, and not by the ulnar, by whose under side it runs to the elbow-joint.

The afferent nerves enter the vessel always at an acute angle, and should a portion of the vessel-wall immediately surrounding the point of entrance not be supplied directly, a recurrent branch is always given off, for this purpose, from the first subsequent division of the nerve. In no case was seen a short branch breaking immediately into fibres to be distributed upon the surface of the vessel, as has been described by D. Lucae;* on the contrary, a branch will accompany the vessel for some distance before entering its wall. The distribution of a nerve is generally in one plane,—i.e., if a supplying nerve runs along the superficial aspect of a vessel, it will continue thereupon to its terminal division (macroscopic).

The nerves accompanying the superficial veins are small, both on account of their structure and the facility of obtaining branches from the subcutaneous nervous mesh-work that envelops the entire arm. The cephalic vein, however, is an exception; in its upper portion it is accompanied by a branch of the posterior cutaneous nerve from the radial, to which it owes its innervation. Only one case was seen in which a plexus was found surrounding a vessel, and this was the basilic vein.

The arteries and their accompanying deep veins are furnished with larger and longer nerves, and their supply is generally taken from the nearest trunk. Thus the brachial, in the arm, is supplied by the median nerve; in its upper portion it is innervated by a branch from the brachial plexus; below its division we find that the ulnar artery and vein are accompanied and supplied

by the ulnar nerve. The radial artery, from its origin, runs a short distance without any accompanying nerve before it meets the superficial branch of the radial; to supply this defect a small branch is sent from the median.

As regards the nature of the nervi vasorum, Lucae considered that they were paler and more gelatinous than the other nerves; but they appear to differ in no respect from nerves of different function of similar size and occupying similar protected positions.

The individual anatomical observations are briefly as follows:

The cephalic vein, in its upper portion, is supplied by a branch from the posterior cutaneous nerve from the radial, which accompanies it to the clavicle.

The basilic vein is innervated, as a general rule, partly by the smaller internal cutaneous, and partly by the greater internal cutaneous.

The brachial artery obtains, in its upper portion, a nerve from the brachial plexus; in its lower portion it is supplied mainly by the median nerve, but branches are also returned from the ulnar and radial nerves for its use. A comparatively long branch from the median seems to be quite constant, and runs between the artery and vein on their under side.

The radial artery, in its upper part, is supplied by a branch from the median; lower down, by the superficial ramus of the radial, by means of short branches which enter, without much division, directly into the vessel-wall, principally from its superior aspect.

In the ulnar artery belongs a comparatively large nerve, which was in two instances seen to terminate upon the vessel, and hence is a true nervus vasorum. In one case, this nerve lay upon the vessel; in another, it ran across to the volar side, to take its course along the radial aspect to the wrist-joint; in another, it wound spirally around the vessel to attain the same point.

The superficial palmar arch is supplied sometimes from the ulnar, sometimes from the median, by short branches which enter the vessel from above.

The deep arch is always supplied by the deep ramus of the ulnar.

The arteria pectoralis major is supplied by the nerve of the same name; and the arteries for the pectoralis minor, deltoid, and supra-scapular muscles are also supplied by nerves of corresponding names.

The scapular circumflex artery and vein are innervated by the superior branch of the thoracico-dorsalis.

The first collateral branch of the ulnar has a branch not from the ulnar but from the radial (Wenzel-Gruber).

The interosseous artery and vein derive their supply from long branches of the interosseous nerve. The perforating branches of these vessels are innervated by the deep ramus of the radial nerve.

A plate exhibiting the different methods of innervation of the vessels and the distribution and termination of the nerves accompanies and illustrates the article.

F. W.

MUSTARD FOOT-BATH IN URTICARIA.—A writer in the *Tribune Medicale*, March 7, recommends the use of the mustard foot-bath in cases of urticaria. In his own case, after trying innumerable remedies, he was about to abandon all hope of relief, when, one day, while suffering from a peculiarly aggravated attack of his old enemy, complicated by an excruciating headache, and hoping to relieve the latter, he plunged his feet into a mustard-bath. The relief was instantaneous, and it seemed as though the skin-disease had disappeared by a wave of the hand.

Five other cases were subsequently treated by the writer, with similar relief. The treatment is, of course, understood to be only palliative, and has no influence in preventing recurrence of the disorder.

SATURDAY, MAY 1, 1875.

EDITORIAL.

THE SO-CALLED SYMPATHETIC NERVOUS SYSTEM.

THERE is an old saying that "Truth crushed to earth will rise again;" but the trouble with error often seems to be that human power cannot crush it. For many years the so-called sympathetic nervous system has been the ever-ready slop-shop of the baffled pathologist, out of which he has drawn ready-made explanations for all the more recondite diseases of the human system. To be sure, the garments often did not fit very well, and the winds of controversy swept through their numerous rents with chilling force, yet to many minds a sham seems better than the open nakedness of confessed ignorance. Recently those imaginative children of the present—the electro-therapeutists—have also availed themselves of this mysterious entity, and by galvanization of the sympathetic have cured all manner of human ills, almost making, according to their own reports, the blind to see, the deaf to hear, and the lame to leap as a hart. If, however, there be anything at all established by modern investigations, it is that the sympathetic nervous system is a human invention; yet teachers and writers still continue to wrap themselves in the tattered rags of old opinions, physiological text-books drive more deeply the fastenings of error by elaborate chapters on the subject, and even the greatest of all English prizes is offered in the year of our Lord 1875 for an essay on the "Diseases of the Sympathetic Nervous System."

Surely, then, our readers will pardon our occupying a brief space with the discussion of this Old-World myth.

The name sympathetic is a highly suggestive one, redolent, in its mysterious, undefined comprehensiveness, of those mediæval days when "nature abhorred a vacuum." In itself it has been a priceless treasure to those who were determined to explain everything, and a stumbling-block in the way of those who, with the true humility of modern science, contend that it is better to leave the unknown as unknown than to theorize far beyond the known facts. It is so easy to talk grandiloquently concerning the sympathies of the organs and this wonderful net-work of nerves that permeates and unites them all. The offspring of error, the name has become the progenitor of error. But let this pass; accepting the appellation as hopelessly fixed by custom, let us inquire as to the existence of the thing named.

There are undoubtedly in various parts of the body certain anatomical structures—masses of ganglionic nerve-matter connected by nerves and giving off nerves—to which the term has been applied. The question is not, however, whether there are any structures, but whether these constitute a nervous system capable of independent action and having a unity of function.

A nervous system must of course contain afferent nerves running from the periphery to the centre, which receives their transmitted impulses, and sends them back through other nerves to the periphery again. A nerve and a ganglion do not form in themselves a nervous system, else the posterior roots of the spinal nerve and their ganglia are worthy of such dignity. Where, then, is the afferent nerve of the "sympathetic nervous system"? In the posterior spinal nerve-roots and their continuation as the ordinary nerves of sensation alone exist any nerve-fibres which are capable of transmitting a peripheral irritation so that it may reach the sympathetic ganglia. In other words, the afferent nerve of the so-called sympathetic system is a cerebro-spinal nerve passing up into the medulla oblongata. If this nerve and its connection be intact, an impulse started in its periphery passes up to the medulla, down again through the cord, out with an efferent cerebro-spinal nerve, and on through one or more of the so-called sympathetic ganglia to the vessels of the body, producing a contraction of them. If the spinal nerve be cut, if the spinal cord be divided, or if the efferent spinal nerve or the so-called sympathetic ganglion be injured, the impulse which has started at the periphery of an ordinary nerve is unable to reach the vessel and produce its

effect. In other words, there is here a true physiological nervous system,—the vaso-motor,—anatomically composed of an ordinary sensitive nerve, a portion of the cerebro-spinal axis, an efferent spinal nerve, and a sympathetic ganglion with its nerves. The so-called sympathetic nervous system forms merely a subordinate portion of this complete system, which is in its origin cerebro-spinal.

Nor is there in the sympathetic ganglia any unity of function. It has recently been established that there is a nervous system that controls calorification,—*i.e.*, nutrition or the chemical movements of the tissues,—independent of the circulation and respiration. If this is to be acted upon, it is an ordinary spinal afferent nerve that transmits the impulse to the chief centre of the system, which is placed somewhere at the base of the brain. The outward track of this impulse is down through the spinal column, out along the spinal nerves, and in all probability through the sympathetic ganglia to the various organs and tissues of the body.

Again, if the upper cervical sympathetic ganglion be divided, the iris contracts; if it be stimulated, the iris dilates; if the thoracic ganglia be injured, the heart manifests the result; and the intestinal movements are directly under the control of the splanchnics.

Evidently the so-called sympathetic ganglia are only portions of various physiological nervous systems, and are nothing but reinforcing nerve-masses situated upon the tracks of efferent nerves, corresponding, it may be, to the posterior spinal ganglia on the afferent nerves.

If we view the human organism from an anatomico-physiological stand-point, there is evidently but one nervous system,—namely, the cerebro-spinal,—since all centres in the cerebro-spinal axis; but if we adopt a purely physiological point of view, there are a number of nervous systems, all finding their centres within the cranium. Of several of these—the vaso-motor, the cardiac, the intestinal, and the chemical—the sympathetic ganglia evidently form a part. It will probably be found that these outlying nerve-masses are also connected with nervous systems not yet known. The only safe method of progress is, however, simply to make the best use of known facts, not to build theories out of the mere pasteboards of imagination. It is high time, therefore, that we ceased to speculate concerning the sympathetic nerves, discussing simply the influence of vaso-motor, chemical, and other nerves, and trying, by experiment, to discover what else of importance there is in that tangled bundle of possibilities, the so-called sympathetic ganglion.

DR. THOMAS G. MORTON has called upon us with reference to the recent editorial containing a quotation from his article in regard to the statistics of the Pennsylvania Hospital. He says that he believes that in certain states of the weather in summer there is no movement of the air, and consequently no ventilation, even if all the windows be open, and he claims that in the Pennsylvania Hospital the windows are not sufficiently large or abundant, and, moreover, are so high from the floor as to leave the lower strata of air to a certain degree, as it were, in a well,—a fact which first led him to advocate the forced ventilation. He also says that he has made calculations based on the statistics of forty-five years, which appear to show that the “apparent fallacy in the statistical argument” we pointed out is more apparent than real. Thus, dividing the year into two six months,—from May to November, and from November to May,—there have been in the forty-five years, during the winter months, 359 cases, with 86 deaths, giving a percentage of $24\frac{5}{100}$; during the summer months 522 cases and 143 deaths, yielding a mortality rate of $27\frac{2}{100}$ per cent. These figures speak for themselves. In regard to our not being able to consult the hospital records, it appears that during ten years Dr. Morton kept himself the only records of amputation, so that the hospital cannot show what it does not have,—a fact that does not speak in thundering notes of praise in favor of the organization or executive management of this portion of the hospital surgical service. The subject is rendered even more difficult by this want of public records; but, correct or incorrect, our editorial has been of service, since it has led Dr. Morton to promise us at some not far distant day a careful and elaborate paper on the subject.

MR. G. W. CALLENDER, F.R.S., a distinguished London surgeon and one of the staff of St. Bartholomew's Hospital, says in a letter to a surgical friend in this city that he will probably visit this country during the latter part of the coming summer. Mr. Callender is well known for his original surgical observations and as an able contributor to periodical medical literature, and the profession of America will be glad to extend courtesy to him.

At a meeting of the County Medical Society held just after the last number of the *Times* had gone to press, Dr. William Pepper brought forward a motion to invite the American Medical Association to meet in Philadelphia next year. After considerable discussion, in which it was quite plainly shown that the intention of some had been not to

take such action, it was decided unanimously to invite the Association, asking it at the same time, however, to postpone its meeting until June.

CORRESPONDENCE.

BALTIMORE, April 24, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—For five days the attention of the medical profession was occupied by the meetings of the Medico-Chirurgical Faculty, which is our State Society. The sessions began on April 12, and terminated on the 17th. Much interest was shown in the proceedings, as was evident by the large attendance.

The regular reports presented by the officers and standing committees indicate that the faculty is in a flourishing condition. The report from the Library Board recommended adding late works to the collection of Noachian volumes now on hand, securing a pleasant reading-room, and the publication of a monthly journal. Everybody knows that it is an *extremely easy* matter to start a journal, but whether a resolution from any medical body can make it a success remains to be seen. The history of medical papers in this State has been so unfortunate that individuals and societies would do well to count the cost before making the venture.

The report on Surgery was presented by Prof. Thos. R. Brown.

Dr. J. M. Toner, of Washington, delivered the Annual Oration, on the Topography of Maryland as affecting Health. Regret was expressed that the facts collected by the U. S. Census bearing upon vital statistics have not been reported by the smaller political divisions of cities and counties, instead of merely by States and districts, as the omission impairs their usefulness for comparison. To meet the want, however, he presented a table prepared to show the full number of physicians employed in the State, and the extent of their fields of labor. In 1850 the population was 583,034, of whom 990 were physicians,—a proportion of one to every 588 of the population. The total mortality was 9621. In 1860 the population was 687,049, of whom 1093 were physicians, being one to every 628. The mortality was 7374. In 1870, population 780,894, physicians 1257, or one to 621. Mortality 9740. A lengthy description of the topographical and geological condition of the State was given, dwelling upon the malaria that infests certain portions. He thinks that drainage would relieve many parts of the State of this cause of disease. For this purpose he recommended that the legislature should be requested to appoint a competent civil engineer to act in conjunction with the State Board of Health, of which body he should be a member. He should make a complete survey of all the swampy, badly-drained, and water-soaked lands of the State, and suggest measures for abating the nuisance. The doctor closed his address by making a complete review of the various surveys made throughout the State, and warmly commended the western section as being as healthy a

region for summer resort as there can be found in the United States.

The report from the section of Materia Medica was presented by Prof. McSherry. He spoke at length on calomel as a cholagogue, quinine in the summer diseases of children, hæmatoxylon in membranous enteritis, kousso and sulphur in tapeworm, and ergot and phosphoric acid in some diseases of bladder and rectum.

Dr. G. H. Boyland read a paper on "Cases in Foreign Hospital-Practice." The cases were interesting; but why a paper made up of cases copied from medical journals should be read as an original paper I cannot see.

Prof. F. T. Miles and Dr. I. E. Atkinson both read papers of some interest.

"Tinnitus Aurium," by Dr. Theobald, was an interesting paper. He thinks that tinnitus is produced by the vibration of the walls of the blood-vessels, produced by friction of the circulating blood, which excites the terminal filaments of the auditory nerves.

Prof. Chew read a paper on "Digitalis in Heart-Disease."

The report on Obstetrics and Gynæcology, by Prof. W. T. Howard, was long and dry, and not very new. When I mention the fact that he kept the floor for three hours, you may know the audience was exhausted, if the subject was not.

The officers for the year are: President, Dr. J. F. Monmonier; Vice-Presidents, Drs. C. Johnston, A. B. Arnold, J. C. Thomas; Recording Secretaries, Drs. W. G. Regester and G. L. Taneyhill; Treasurer, Dr. J. Gilman. Chairmen of the Sections: Surgery, Dr. C. Johnston; Practice, Dr. A. B. Arnold; Obstetrics, Dr. W. T. Howard; Materia Medica and Chemistry, Dr. D. J. McKew; Meteorology, Dr. E. Lloyd Howard; Anatomy and Pathology, Dr. H. R. Noel; Psychology and Physiology, Dr. J. S. Conrad. Drs. N. P. Smith, J. F. Monmonier, John Morris, C. Johnston, F. Donaldson, J. J. Cockrill, A. Hartman, P. C. Williams, S. C. Chew, J. Gilman, A. B. Arnold, A. F. Erick, E. L. Howard, G. L. Taneyhill, F. T. Miles, H. R. Noel, W. G. Regester, T. S. Latimer, C. H. Jones, L. Ellicott, J. C. Thomas, J. A. Stewart, D. J. McKew, W. C. Van Bibber, T. R. Brown, R. Buckler, R. McSherry, and H. T. Rennolds were appointed delegates to the American Medical Association. The meetings of the Faculty have improved in interest very much with the last few years, but they might be much better if gentlemen could learn the art of condensing. Some of the memoirs were much longer than the subject justified, and many papers were, on account of want of time, referred to the Committee on Publication unread. I had intended to say something about the Johns Hopkins Hospital and University, but must defer it until next time.

Yours, etc.,

MEDICUS.

Harvard University now requires a preliminary examination, or its equivalent, before entrance of the medical department.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, FEBRUARY 25, 1875.

THE PRESIDENT, DR. H. LENOX HODGE, in the chair.

DR. H. S. SCHELL presented a specimen of *atresia vaginae*, which is reported in full in another column of the current number of the *Times*, together with the report of the Committee on Morbid Growths.

Dr. H. LENOX HODGE remarked that one point of practical interest was whether the aspiration had anything to do with causing death. He had himself many times passed a needle into the abdominal cavity, both from the vagina and through the abdominal walls, and had never had the slightest accident to result. He was glad to find that Dr. Schell did not ascribe the death of the patient to the aspiration, but to the peritonitis caused by the rupture of the cul-de-sac.

Dr. SCHELL said the examination was made under the influence of ether, of which a very large quantity was used,—more than a pound. The patient resisted etherization so violently that at one time a large portion of the tumor protruded through the anus, looking not unlike a child's head, and he thought it probable that at that time the rupture took place. There was no great force used by the surgeons in their manipulations, because rupture was anticipated.

Dr. HODGE further called attention to the band of tissue running through the sac of the vagina, separated and isolated from the surrounding structures, save at its extremities; also, to the fact that the Fallopian tube appeared to enter the uterus at one side near its middle, and at the other in its usual place.

Dr. SCHELL called attention to the interesting fact that the neck of the uterus was dilated much more than the body, whereas one would suppose that the body would be the portion most dilated in retained menses.

Dr. HODGE said he had had no experience in retained menses, but he had often heard his father express surprise at the little effect the retention seemed to have upon the uterus, and that in his cases the distention was almost entirely that of the vagina, while the uterus was very little enlarged, floating, as it were, above the blood. In this instance, however, not only the vagina, but the major part of the uterus also, was enlarged.

REVIEWS AND BOOK NOTICES.

A STUDY OF FEVER. The Toner Lecture for 1875. By HORATIO C. WOOD, M.D. Smithsonian Institution. (Kept on sale by J. B. Lippincott & Co. Price 25 cts.)

This pamphlet is as well worth reading by thoughtful physicians as anything which has lately passed under our eyes; and whether or not we differ with its able author as to his conclusions, no one can fail to feel that the argument is most intelligent, and that the experiments are devised by one who has a gift for research which needs only use to become of the utmost value to medicine. Dr. Wood wishes to prove that fever is heat and its consequences,—or that heat will cause all the phenomena of fever; that local application of heat causes such functional disturbances as are familiar to us in fever; that to lessen heat is, in fever, to relieve such functional symptoms. Then follow Dr. Wood's details of his former experiments on the fatal influence of heat. Here we want somewhat experiments on the prolonged subjection of animals to a moderate

heat; and we still lack throughout all the proof that artificially-induced fever increases the chemical products of the body, and that such products are akin in the fever of disease and that of the laboratory.

Dr. Wood next asks in what way the febrile rise of temperature is caused, and shrewdly puts the question on p. 12 as to hæmic or neurotic parentage for fever, concluding that there is a neural "fever-centre," and that it is this which is influenced, directly or indirectly, by so-called hæmic poisons. The discussion which follows as to like production of local fever and of urethral fever is especially interesting. Then comes a series of experiments to prove that the fall of temperature caused by irritation of a sensitive nerve is independent of the circulation,—that is, the change is not due to lessened blood-flow, and, if not, is due to direct influence of the nervous system upon the heat-producing function of the body. Dr. Wood next states the facts in sequence leading up to his own contributions. They are these: Section of the spinal cord in the neck causes—first, a slight fall, and then a rise of temperature to fever if the animal be kept warm,—as in a box or covered with cotton,—but unhurt animals so placed do not grow overheated. Section of cord between the medulla oblongata and the pons Varolii gives immediate rise and no fall of temperature. These latter facts rested on one experiment by Tscheschichin, and have been thoroughly reproven by Dr. Wood, who also seems to show pretty clearly that this operation leaves the vaso-motor centres in the medulla oblongata untouched, because they are below the point of section.

Dr. Wood concludes from these facts that the vasal disturbance has no share in the fever of spinal sections, as to which it is but just to add that so pregnant a conclusion can hardly be accepted without much more and much more varied evidence; nor will it be complete until, by some rapid means, as the thermo-multiplier, a rise in temperature after spine-section can be seen in limbs devoid of blood. If by an Esmarch bandage a limb were emptied of blood, and then found to rise in heat ever so little after spinal section, the case for a centre-controlling chemical activity, not alone through vasal dilatation and contraction, would be well made out.

In Dr. Wood's next corollary he follows Tscheschichin, and thinks with him that above the medulla oblongata must lie a centre capable of lessening chemical action, and, of course, with it the product of heat. As concerns this point, it may be well to remark that it is hard to get away from the idea of ordinary nutritive chemical activities, and that whoever deals with the question of the heat-making chemistry cannot escape from considering, in its relation to them, the questions as to nutritive centres, which, if they exist, must be more or less regulative of heat-product.

The remainder of this very able paper is chiefly taken up with illustrations from disease, meant to show how completely the idea of an inhibitory heat-centre explains its thermal phenomena. We are, however, not quite of Dr. Wood's opinion that cerebral rheumatism is "completely cleared up" by this theory. It is, of course, possible that rheumatism may fall on the centre in question and paralyze it; but the first effect ought to be, one would think, irritative, and should call out an explosion of inhibitive force which would be seen as lowering temperature, and only raise it when the palsy-point was reached. Then, also, it seems strange that no other brain-malady which affects these centres seems to create the enormous rise of temperature due to rheumatism. The difficulties which gather thick about this subject are admirably illustrated on p. 34 of a most masterly clinical paper upon cerebral rheumatism, by Prof. Da Costa, *American Journal of the Medical Sciences*, January, 1875.

Dr. Wood has certainly pointed thought in a new

direction, and has begun what we hope to see him complete, for no subject in the range of physiology promises more to a worker so ingenious and so fertile in experimental resources.

S. WEIR MITCHELL.

THE HISTOLOGY AND HISTO-CHEMISTRY OF MAN. By HEINRICH FREY. Translated from the Fourth German Edition by ARTHUR E. J. BARKER, Surgeon to the City of Dublin Hospital. New York, D. Appleton & Co.

The present volume is by no means a new acquaintance; it is rather an old friend in a new dress. We have long known the original German work as on the whole probably the best that exists for the use of the average medical practitioner, or the special student of the subject during his earlier studies. A somewhat cursory examination of the volume before us has led us to the opinion that the translator has done his work well. The printing and proof-reading also are good, and we can therefore commend the work most highly to the attention of our readers.

A COURSE OF LECTURES ON PHYSIOLOGY, as delivered by PROF. KUSS at the Medical School of the University of Strasbourg. Edited by MATHIAS DUVAL, M.D., formerly Demonstrator of Anatomy at the Medical School of Strasbourg, etc. Translated from the Second Revised Edition by ROBERT AMORY, M.D., formerly Professor of Physiology at the Medical School of Maine, etc. Illustrated by 150 wood-cuts inserted in the text. Boston, James Campbell, 1875.

We hail with pleasure the appearance of this work, as furnishing the first exposition in the English language of what may be termed the modern physiology. Notwithstanding the numerous text-books on this subject now extant, there is not one, with the exception of this just issued, which affords the student an opportunity of becoming familiar with the new aspect which physiology has acquired in the past ten years. Further, with few exceptions, the entire subject in its different departments is equally considered—no undue proportion of space being devoted to one to the exclusion of another—in little more than five hundred moderate pages, so that the student can easily compass its extent in the time allotted him.

The author very properly begins the first part with general physiology,—cellular physiology,—and, after a somewhat clumsy effort to define physiology, takes up *the cell*, which he indicates indifferently by the latter term and the word *globule*, to which we object emphatically. For although the correct notion of a cell in its active, growing state makes it anything else but “a cell” or *vesicle* in the strict sense of the word, and although it is really a clump or mass of *living* matter, the word *globule* has become so closely associated with a spherical mass of *dead* material either of microscopic size or larger, and, under the former circumstances, presenting such well-defined characters under the microscope,—those of a bright centre and dark outline, the width of the latter being directly as the difference in the refractive index of the globule and the menstruum in which it floats,—that it seems like retrogression to reapply it to the “elementary part.” While the term “cell” is also objectionable for the above reason, it is less so than the word “globule,” because there is a period in the history of many cells at which they are *vesicular*, and it has, moreover, become so engrafted upon histology that there is some justification for its use. We much prefer, however, the term “elementary part,” which not only does not clash with our present idea of the anatomy of the cell, but will also be in accord with any future modification of it.

The *second* part of the book is devoted to the nervous system; the *third*, to contractile elements,—muscles and

their appendages; the *fourth*, to the blood and its circulation; the *fifth*, to a general view of epithelial globules and epithelial surfaces; the *sixth*, to the *digestive system*; the *seventh*, to pulmonary mucous surface, respiration, animal heat, and phonation; the *eighth*, to the external integument; the *ninth*, to the organs of special sense; and the *tenth*, to the uro-genital system and embryology. In the last, the view adopted of the minute structure of the kidney is not that which seems clearly established by the latest researches of Ludwig and Henle, as well as the earlier ones of Todd and Bowman. By the author the Malpighian body is described as formed by a surrounding of the Malpighian tuft by the Malpighian capsule, in a *depression* of the capsule, the two surfaces of the latter being closely opposed, and the whole capsule folding over the tuft somewhat as the pleural sac embraces the lung, the afferent and efferent vessels bearing the same relation to the capsule as the root of the lung does to the pleural sac, instead of perforating it as is generally taught.

With regard to the secretion of urine, also, Küss adopts the somewhat singular view of Wittich, that it is a filtration of *all* the constituents of the liquor sanguinis, *including the albumen, which is, however, re-absorbed by the epithelial cells* of the uriniferous tubules beyond the Malpighian capsule. While there is no doubt that a large part of the act of secretion of urine is accomplished by the processes of filtration under pressure and of osmosis, we cannot believe that in health the albumen is forced through the walls of the blood-vessels as it is in disease; while we further prefer to adopt the intermediate ground, according to which the water and inorganic salts of the urine are obtained through filtration and osmosis; but the organic constituents, urea and allied substances, are added through a *secretory* action of the cells.

While all that we have said in favor of this work, to which we have devoted more than our usual amount of space, is strictly true, and while, on the whole, we find in it a book better adapted to the wants of the student than any other in the English language, yet it is far from being a perfect text-book, and in this we are glad that its able translator, Dr. Amory, agrees with us.

In the first place, as Dr. Amory says in his preface, too much prominence is given (we mean for the purposes of the student) to the author's peculiar views, to the exclusion of others; second, it lacks that clearness of expression and sharply-defined systematic arrangement which is so necessary for the student, while there is sometimes so much ambiguity in the language used that even those who have some knowledge of physiology cannot always arrive at the author's meaning. These are serious defects in a text-book. They may be, in part, due to the difficulties in translation. Of this we cannot be certain, as we have never seen the book in the original; but we think so practical a physiologist as Dr. Amory would have been justified in sacrificing literalness of translation to clearness of meaning.

A few errors which have escaped the proof-reader, such as the use of singular verbs with plural nominatives (p. 27), the substitution of the words “spinal canal” for “spinal cord” (p. 34 at end), and some others, we hope the translator may have an opportunity to correct in an early second edition.

J. T.

QUADRUPLETS.—The *Lyon Medical* states that the Countess Schlippenbach, in Croatia, was lately delivered of four children, three girls and one boy. A woman of the name of Latouche, of Saint-Roch, near Quebec, is also mentioned as having given birth to four fine boys. The paper does not state whether these children lived.

SELECTIONS.

SPECK ON DEATH FROM A RATHER HIGH TEMPERATURE.—C. Speck publishes a case in Eulenberg's *Vierteljahrsschrift für gerichtliche Medicin und öffentl. Sanitätswesen*, vol. xxi., quoted in *Centralblatt für die Medicinischen Wissenschaften*, Feb. 27, 1875, of death which he attributes to a high temperature. A girl aged seventeen, who had suffered for eight years from contractions of all her joints, was enveloped, as a remedial measure, in the skin of a sheep just killed, then surrounded with fresh-baked hot bread, and a covering thrown over all. She complained after an hour of feeling uncomfortable, and of pain, then sank into sleep, then had difficulty of breathing, and perspired a great deal; lastly, became pale, and died about three hours from the beginning of the 'cure.' The most marked feature of the necropsy was advanced decomposition, although the surroundings were not favorable to this. The finest vessels in the pia matter were injected, whilst the larger were almost empty of blood, but contained air [*sic*]. The heart and large vessels were almost bloodless; the pericardium contained frothy fluid. The walls of the heart were pulpy, and studded with punctiform ecchymoses. The medico-legal report was to the effect that, in the absence of any other cause of death, the advanced decomposition pointed to decomposition of the blood, and that death was probably due to the so-called 'cure.' Reference was made to the investigations of Bernard and Ackermann, showing the injurious effects of temperatures equalling or exceeding the normal temperature of the body. Speck satisfied himself that bread exposed to the air in a room at the temperature of 16° or 17° (60° to 62° Fahr.) had, after two hours, a temperature of 45° (113° Fahr.) in the interior. [The reporter thinks it far more reasonable to attribute this death to the carbonic acid, etc., given off from the bread, especially as he knows of a somewhat similar case which occurred in the country some years ago, when death, with all the signs of suffocation, followed from a similar procedure advised by a quack. It is also well known that accidents of this kind used to occur to journeymen-bakers some years ago. The empty condition of the heart and great vessels was, no doubt, due partly to the youth of the victim and partly to decomposition.—*Rep.*]—*W. Bathurst Woodman, M.D., in London Medical Record.*

GLEANINGS FROM OUR EXCHANGES.

TREATMENT OF RHEUMATISM AND GOUT WITH TRIMETHYLAMIN.—Mr. W. H. Spencer contributes to *The Practitioner* (February and March) the results of his experience in the use of this remedy.

After giving a brief *résumé* of the chemical history and properties of the drug, he gives the notes of a number of cases, treated either with the somewhat impure trimethylamin (called propylamin in commerce) or with the synthetically-prepared chloride of trimethylamin. The dose employed varied much: it ranged from nine to thirty minims for the solution, and did not exceed ten minims for the salt.

As supporting the probability of variation in composition, Mr. Spencer, at different times, found that the same results were obtained with a dose of two minims as with a dose of eight. His method of administering the drug is in doses of four to eight minims, at first every hour or two hours, increasing the interval as the pains diminish and the case progresses. When all pain is gone he ceases to give the remedy, and substi-

tutes in most cases quinine. He rarely has to re-exhibit the trimethylamin, but does so if the pains recur. Mr. Spencer's cases are sixty in number, of which notes are given in twenty-one, including cases of acute and chronic rheumatism, gout, and gonorrheal rheumatism. In the latter, trimethylamin seemed to have only a temporary effect. In the others its effect was always beneficial,—sometimes remarkably so. The chloride failed in a number of cases, and the solution ("propylamin," so called) had to be substituted.

Continental observers have stated that under the influence of trimethylamin the amount of urine excreted is increased, whilst the amount of urea excreted is diminished. M. Bouchard found that one of the physiological effects of trimethylamin was diminution in the excretion of urea. It has been observed that a sudden and inexplicable increase in the amount of the urea excreted is liable to occur during the use of trimethylamin. All of these observations are confirmed by Mr. Spencer's experiments. Among the unfavorable effects of the remedy may be mentioned certain nervous symptoms and headache, occurring in some cases; in others, gastric disturbance and diarrhoea were brought on even while the remedy continued to do good. In one or two cases the use of trimethylamin seemed to exercise a pernicious effect upon certain intercurrent sores, causing sloughing, which was only healed when this drug was discontinued. The remedy appears to exercise but little influence on the course of the fever, as indicated by the thermometer, in opposition to the views of Continental observers. On the other hand, it appeared in many cases as if the cardiac symptoms were actually aborted.

THE VALUE OF TAR IN BRONCHIAL CATARRH AND WINTER COUGH.—Drs. Sidney Ringer and William Murrill contribute a note on the use of tar to the *British Medical Journal*, March 20. They have employed tar in two-grain doses, made into a pill, every three or four hours. From October to January inclusive its effects were watched on twenty-five patients, whose ages varied from 34 to 70. All these patients had suffered several years from winter cough, lasting the whole winter.

These patients suffered from paroxysmal and violent cough, each attack lasting from two to ten minutes,—recurring ten or twelve times in the day, and breaking their rest at night. Expectoration abundant, frothy, and purulent. Breathing short on exertion, but most could lie down at night without propping. The physical signs showed a variable amount of emphysema, with sonorous and sibilant rhonchus, and occasionally a little bubbling rhonchus at the base. These patients usually began to improve from the fourth to the seventh day; the improvement rapidly increased, and in about three weeks they were well enough to be discharged. The improvement was so decided that even those patients who, in previous years, had been confined to the house during the whole winter, returned to their work. On discontinuing the tar, relapses often occurred in a week or two, but on re-administering the medicine relief was again obtained.

TREATMENT OF NÆVI BY ELECTROLYSIS.—Dr. S. I. Knott reports (*Lancet*, March 20) a number of cases in which he has employed electricity in the removal of nævi from all parts of the body, with great success. He uses Stöhrer's and Meyer and Meltzer's continuous batteries, and judges, according to the size of the nævus, how many cells to use. Six or eight is about the average if the battery is in good working order. If the nævus is small he uses one or two needles attached to the negative pole, and one to the positive, and passes them into the tumor; but if large, he puts on several needles in the negative cord, and uses a charcoal point with the positive. After the needles have been in the

tumor a short time, decomposition begins to take place: this is shown by bubbles of gas passing by the side of the needles. A clot is then formed, the tumor turns of a bluish white, and in this clot fibrous degeneration takes place, and ultimate cure is the result. The advantages of the galvanism are its certainty of action, its safety, the faintness of the cicatrix, and the cessation of pain directly the operation is over.

Dr. Knott has used every other method, but thinks this is by far the best. His communication closes with the notes of thirteen cases, out of some forty upon which he has operated.

CASE OF COXITIS TREATED BY EXCISION.—The following case is reported by Mr. Hulke in the *Lancet*, March 20. A lad of 19 was admitted into the Middlesex Hospital, with coxitis of about twelve years' duration. The left lower extremity was very much wasted, the thigh strongly flexed and adducted, and very firmly ankylosed to the pelvis. He complained much of pain in the knee and hip, aggravated by the least attempt at passive movement or pressure on the hip. The leg was flexed at about 90°, and the knee contracted. The left thigh was fourteen inches long, the right, seventeen and a half inches. There were scars of former abscesses about the hip. The disease dated back to a fall twelve years previously. Various abscesses formed from the time of his admission, March 6, 1874, until May 6. At that time resection of the head of the femur was performed, a drainage-tube was inserted into the acetabulum, and the wound closed, after having been washed out with chloride of zinc. The bent knee did not allow the application of a splint; extension and fixation were therefore maintained by straps, cord, and weight. The patient rallied slowly, and lingered through the summer until October, when it was decided that his only chance lay in an amputation at the hip-joint. This operation was therefore performed; lateral skin-flaps being cut from without and reflected, and then the muscles divided, circularly, close to the face of the pelvis (Guthrie's method). The wound healed kindly, and the patient still survives, March 20, 1875, with a good chance of ultimate recovery.

LADIES' RETIRING-ROOMS IN LONDON.—A company has been formed in London for the purpose of establishing ladies' retiring-rooms. It having been suggested in the *Lancet* that certain risks would be run at such establishments, the secretary writes to the editor of that journal as follows:

"SIR,—The gentlemen who have associated themselves to form a company for the purpose of establishing ladies' retiring-rooms, etc., are much indebted to you for the notice of their project which you were pleased to give in your issue of January 16. With reference to your concluding remark as to the risk which ladies might run of contracting a contagious disease, those gentlemen would be glad of an opportunity of stating in your columns, for the information of 'parents and husbands,' what they could not very well set forth in their printed scheme,—namely, that it will be insisted on that the matron in charge will see, immediately after any closet is used, that it is well cleansed and dried, and in all respects made fit for subsequent use. In order that this may be effectively carried out, as large a number of closets as possible will be fitted up at each of the resting-places. Moreover, it is in contemplation to introduce more than one *description* of convenience, and large sheets of paper will be provided for placing over the seats if desired, and other similar provisions will be made. For example, a large number of *false seats* might be prepared at comparatively small cost, very light, and capable of being readily washed all over, so as to allow of a perfectly clean and dry seat being available for each visitor. The

main seat of each closet will be of highly-polished wood, probably mahogany, and glazed tiles will be very freely employed. The gentlemen associated with me are well assured that the success of the undertaking will depend in great measure upon one thing, and that is *cleanliness*. With thanks on their behalf,

"I remain sincerely yours,
"TOM NICHOLS,
"Hon. Sec. to the proposed Company."

TREATMENT OF FRACTURED PATELLA.—*The Practitioner* for March contains three short communications on this subject, by as many surgeons. Mr. Spence recommends a modification of Malgaigne's hooks, these being fastened in strips of moleskin adhesive plaster cut out carefully to fit the skin, and attached above and below the knee. By this means the irritation caused by inserting the hooks into the live integument is avoided.

Mr. Callender, of St. Bartholomew's Hospital, treats fracture of the patella by a peculiar arrangement combining the swinging splint with the pulley and weight. The latter is attached to plaster strips, fastened below and above the knee, so that its weight pulls them together. Cuts are given illustrating both these plans of treatment. The third method, called the "expectant," is advocated by Mr. McGill, Surgeon to the Leeds Public Dispensary, as Mr. Teale's treatment. Mr. Teale simply places the leg on a pillow slightly bent between sand-bags, or on a straight splint, with the heel slightly raised, and the patient is confined to bed for six or eight weeks, and then when allowed to get up is fitted with a soft leather splint, which will limit but not arrest the movement of the joint. Mr. McGill advocates a somewhat similar treatment for fracture of the olecranon, using a rectangular splint.

SUCCESSFUL LIGATION OF THE COMMON CAROTID.—Dr. N. B. Kennedy (*Am. Med. Weekly*, April 10) was called to see a man, sixty-three years of age, who had, with suicidal intent, taken two ounces of laudanum, and a few hours later cut his throat with a pocket-knife. On examination, a transverse wound was found, about two and a half inches in length, extending from near the trachea to the outer border of the sterno-cleido-mastoid muscle of the right side. The common carotid artery had been severed at a point just below where it is crossed by the omohyoid muscle. The sheath of the artery had been opened for an inch or more; the descendens noni nerve and jugular vein were uninjured. A single ligature was passed around the vessel with the aid of an aneurism-needle, and tied with a double knot; one end being then cut off, and the other allowed to hang out of the wound. The external wound was closed by three interrupted sutures, and cold-water dressings were applied. The patient made a remarkably rapid recovery. On the morning subsequent to the operation he rose and dressed himself, declaring that he felt well, but weak; on the third day he went out riding, and the complete cure was effected in a very short time.

ERGOTIN IN FIBROID OF THE UTERUS.—Dr. Bartholow (*The Clinic*, January 23) had recently under his care a case of submucous fibroid of the uterus, for the cure of which he resorted to the hypodermic injection of an aqueous solution of ergotin in one-grain doses night and morning. On the afternoon following the injection the patient began to feel expulsive pains, which continued to increase in severity. After two weeks the injections were practised only once daily.

One week later the pains had diminished in severity, and, on examination, the neck of the uterus was found very much dilated and plugged with a tumor, which was then easily removed by the *écraseur*. The patient fully recovered, and has suffered none since the removal.

NOTES AND QUERIES.

FAILURE OF CHLORAL IN PUERPERAL CONVULSIONS.

WATSONTOWN, PA., April 17, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

Not long since, a number of physicians, through *The Medical Times*, claimed priority in the use of hydrate of chloral for puerperal convulsions, and, impressed by the tone of these claims, I judged we had a specific for the malady.

Several weeks ago I had the misfortune to have a patient attacked, three hours after delivery, with convulsions, violent and frequent (every half-hour regularly). I gave her at once twenty grains hydrate chloral. In half an hour I gave her thirty-five grains more, and in about an hour repeated the thirty-five grains, all of which had no effect on the frequency or severity of the paroxysms. In about eight hours I gave her thirty-five grains more without effect. In from one to two hours thereafter they suddenly ceased without any apparent cause, unless from an application of mustard to the spine, and the patient recovered. The patient was stout, hearty, plethoric, but had flooded considerably after delivery, and was somewhat exhausted.

The only case besides this one I ever treated seemed to yield to morphia and chloroform, while in this I think hydrate of chloral failed utterly. Or was it from an ignorant and limited use made of it? If so, I would be obliged for a hint to that effect. Taking this community, I think I can find at least five women who have survived convulsions for every one who died with them,—all this from varied treatment. Can any of the above aspirants give us an experience where chloral has cured a greater proportion? and, if not, on what do they base its happy effect?

J. J. LEISER.

CANINE SAGACITY, IN A SURGICAL CONNECTION.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—In a letter recently received from Lancaster, where my father resides, it is said:

"A queer thing occurred just now. Father was in the office, and heard a dog yelping outside the door; he paid no attention until a second and louder yelp was heard, when he opened it, and found a little brown dog standing on the step upon three legs. He brought him in, and, on examining the fourth leg, found a pin sticking in it. He drew out the pin, and the dog ran away again."

The office of my father, Dr. Atlee, is not directly on the street, but stands back, having in front of it some six feet a stone wall with a gate. I will add that it has not been possible to discover anything more about this dog.

This story reminds me of something similar that occurred to me while studying medicine in this same office nearly thirty years ago. A man named Cosgrove, the keeper of a low tavern near the railroad-station, had his arm broken, and came many times to the office to have the dressings arranged. He was always accompanied by a large, most ferocious-looking bull-dog, that watched me most attentively, and most unpleasantly to me, while bandaging his master's arm. A few weeks after Cosgrove's case was discharged, I heard a noise at the office-door as if some animal was pawing it, and, on opening it, saw there this huge bull-dog, accompanied by another dog that held up one of its front legs, evidently broken. They entered the office; I cut several pieces of wood and fastened them firmly to the leg with adhesive plaster, after straightening the limb. They left immediately. The dog that came with Cosgrove's dog I never saw before nor since.

WALTER F. ATLEE.

TREATMENT OF NASAL POLYPI.

BALTIMORE, April 21, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR DOCTOR,—I was pleased to see an article in No. 181, current volume of the *Medical Times*, on "Muriated Tincture of Iron a Cure for Nasal Polyp," by my esteemed friend and former colleague, Prof. George Troup Maxwell, M.D., of New Castle, Del. I am able to bear corroborative testimony to its great value in that regard, from my personal observation of its action in destroying and preventing a return of the trouble. The first case in which I used the tincture of iron in the treatment of nasal polypus was that of George Wilson, Esq., of Savannah, Georgia, in 1859, on whom the operation of evulsion had been performed several times, with, as is often the case, only temporary benefit, the polyps returning after each operation in increasing volume, notwithstanding the greatest care in their removal and the most approved subsequent treatment. The patient was a young and healthy man, and had about given up all hope of the radical

cure of his trouble, when the iron-treatment was decided upon. The suggestion for its use, if my memory serves me correctly, came from my friend Dr. Maxwell. The iron in full strength was applied by a camel's-hair brush to the polyps nearest the external nares, and injected; when those came away, diluted one-half to one-third; and retained in contact with those farther on for a minute or two once a day. In a few days every vestige of the trouble disappeared, never to return again. In my hospital experience during our late civil war, several opportunities were afforded for testing the efficacy of this treatment, and always with success.

Very truly yours,

HARVEY L. BYRD, M.D.

THE attention of the municipal authorities, of the censors of the county medical society, or of the proper person or persons, whoever they may be, is called to the following local, taken from a Chambersburg paper. It ought to be ascertained whether the "doctor" complies with the law in Philadelphia:

"WITHDRAWAL OF APPOINTMENTS.—Owing to the recent law which passed the last legislature (approved by the Governor on Tuesday last), regulating the practice of medicine in Pennsylvania, Dr. Darmon has been compelled to withdraw his appointments with patients in this county. He will, however, he requests us to state, continue to treat patients by letter in all parts of the country, if they will send him a description of their cases, as cheaply as if he were present. His address is Wm. Darmon, M.D., No. 1824 Camac Street, Philadelphia."

ERRATUM.

For *urine*, in the account of Neubauer's experiments on salicylic acid, page 376, read *wine*.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM APRIL 20, 1875, TO APRIL 26, 1875, INCLUSIVE.

McCORMICK, CHAS., SURGEON.—Granted leave of absence for four months, with permission to go beyond sea. S. O. 69, A. G. O., April 19, 1875.

SLOAN, WM. J., SURGEON.—When relieved by Surgeon Head, to report to Commanding General, Department of Dakota, for duty as Medical Director. S. O. 73, A. G. O., April 23, 1875.

HEAD, J. F., SURGEON.—To report to the Commanding General, Department of the South, for duty as Medical Director. S. O. 73, c. s., A. G. O.

HAMMOND, J. F., SURGEON.—Granted leave of absence for one month on Surgeon's Certificate of Disability. S. O. 67, A. G. O., April 15, 1875.

BYRNE, C. C., SURGEON.—Transferred from Willet's Point, New York Harbor, to Department of Dakota. S. O. 73, c. s., A. G. O.

FRANTZ, J. H., SURGEON.—Transferred from Department of the South to Military Division of the Atlantic. S. O. 73, c. s., A. G. O.

GIBSON, J. R., ASSISTANT-SURGEON.—Transferred from Department of the South to Department of the Platte. S. O. 73, c. s., A. G. O.

KINSMAN, J. H., ASSISTANT-SURGEON.—Leave of absence extended one month. S. O. 62, Department of Dakota, April 15, 1875.

O'REILLY, R. M., ASSISTANT-SURGEON.—Relieved from duty in Department of the Platte, to report to the President of the Army Medical Board, New York City, for examination for promotion, and, upon its completion, by letter to the Surgeon-General. S. O. 73, c. s., A. G. O.

WHITE, R. H., ASSISTANT-SURGEON.—Leave of absence extended six months, with permission to go beyond sea. S. O. 67, c. s., A. G. O.

ELBREY, F. W., ASSISTANT-SURGEON.—Assigned to duty at Lebanon, Kentucky. S. O. 52, Department of the South, April 21, 1875.

MATTHEWS, W., ASSISTANT-SURGEON.—Transferred from Military Division of the Atlantic to Department of California, and, prior to his departure, to report in person to the President of the Army Medical Board, New York City, for examination for promotion. S. O. 73, c. s., A. G. O.

MUNN, C. E., ASSISTANT-SURGEON.—Transferred from Military Division of the Atlantic to Department of the Platte. S. O. 73, c. s., A. G. O.

COWDREY, S. G., ASSISTANT-SURGEON.—Relieved from duty in the Department of the Missouri, to report to the President of the Army Medical Board, New York City, for examination for promotion, and, upon its completion, by letter to the Surgeon-General. S. O. 73, c. s., A. G. O.

SKINNER, J. O., ASSISTANT-SURGEON.—Leave of absence extended one month. S. O. 69, c. s., A. G. O.

FINLEY, J. A., ASSISTANT-SURGEON.—Transferred from Military Division of the Atlantic to Department of the Missouri. S. O. 73, c. s., A. G. O.

BEDAL, S. S., ASSISTANT-SURGEON.—Transferred from Military Division of the Atlantic to Department of Texas. S. O. 73, c. s., A. G. O.

HAMILTON, J. B., ASSISTANT-SURGEON.—Transferred from St. Louis Barracks, Missouri, to Department of the Columbia. S. O. 73, c. s., A. G. O.

SATURDAY, MAY 8, 1875.

ORIGINAL COMMUNICATIONS.

ON THE USE OF THE OPHTHALMOSCOPE IN THE DIAGNOSIS OF CEREBRAL DISEASE.

Read before the Philadelphia County Medical Society, February 24, 1875.

BY JAMES H. HUTCHINSON, M.D.,

One of the Attending Physicians to the Pennsylvania Hospital.

DURING the winter of 1857-58, the last of my attendance on lectures, I was a frequent visitor to the clinics at the Wills Hospital, where the ophthalmoscope was just then coming into use. But so recent had been its introduction into this city that no one of the then members of the staff could be considered, in the sense now attached to the word, an expert in its use, while there were only one or two who habitually had recourse to it in the examination of the eye. Any one at all familiar with the service of that hospital now, knows how great a change the lapse of a few years has brought about, and how much the ophthalmoscope is at present relied upon in the diagnosis of ocular diseases. I mention the circumstance only to show how short a time the instrument has been in the hands even of ophthalmologists, and in the hope that, since the advantage which is gained from its use by the specialist is admitted by all, I may succeed in proving to those who hear me to-night that the general practitioner needs only to be thoroughly familiar with its use to find it a great aid in the diagnosis of various forms of disease, and especially of cerebral affections. Notwithstanding the published observations of Drs. Hughlings Jackson and Clifford Allbutt, of England, and of various Continental writers, the number of physicians in general practice in this city who have even a fair knowledge of the changes brought about by disease in the appearances of the fundus of the eye is still small.

Unquestionably, a part of this indisposition to use the ophthalmoscope comes from a belief that more difficulties are connected with the examination of the eye than actually exist. There are difficulties, it is true, but these are not greater or more numerous than can readily be overcome by any one who, fully impressed with the importance of the subject, is willing to sacrifice a little time in studying the art of using the instrument. Another objection frequently made to the ophthalmoscope is that it simply confirms the existence of disease which was suspected before, and that it throws no light upon its nature or location. I will cheerfully admit that there is some truth in the latter part of this objection. Many observers make a distinction between the swelling of the disks resulting from congestion in consequence of some obstruction to the return of blood from the eye, and that which is caused by descending optic neuritis. Other ophthalmologists of equal eminence deny that it is possible to recognize this difference during life. In fact, it is doubtful whether there is not in all cases of

so-called choked disk dependent upon congestion, if of long standing, more or less optic neuritis, so that all that can be truly said is that the existence of an appearance of exudation in the swollen disk early in a case indicates optic neuritis rather than simple choking.

Before advancing farther into my subject, it may be well to pause for a few moments to explain what is meant by a choked disk. In a normal eye the optic papilla is on a level with the retina, immediately surrounding it, and is well defined by the sclerotic ring. The retinal vessels which enter the eye with the nerve bear a definite relation, as regards size, to one another, the veins being slightly larger than the arteries. When choking of the disk exists, the ophthalmoscope shows it to be swollen and to project into the cavity of the eye. The veins become large and tortuous, curving over the sides of the disk, the outlines of which are, in marked cases, wholly lost. The disk presents a striated appearance, which is due to swelling of the nerve-fibres. If neuritis is present, there will be seen, in addition to these appearances, an exudation of lymph, concealing portions of the vessels. The choking of the disk is, therefore, to be regarded as an indication that there is an impediment to the return of blood from the eyeball. A variety of opinion is still entertained in regard to the pathological conditions giving rise to choking of the disk. The fact has already been alluded to that many regard it as the result of descending neuritis. But this explanation will not meet all cases. In a certain number of instances it appears to be almost certain that the inflammation is the consequence and not the cause of the choking. Benedikt believes that its exciting cause is an irritation propagated from some point in the brain which is the seat of disease,—a tumor, for instance,—through the vasomotor nerves to the vessels of the disk. The more generally received opinion appears to be that it is the direct result of pressure, either, as it is held by some, upon the sinuses of the cranium, or, as it is thought by others, upon the sheath of the optic nerve. The pressure of a tumor or of inflammatory products upon the cavernous sinus of either side would cause a retardation of the flow of blood, not merely upon the affected side, but also, in consequence of the free communication between the sinuses of the two sides, upon the other. The compression of the sheath of the optic nerve would give rise to an accumulation of the arachnoid fluid, which would in its turn react upon the veins. The choked disk is, therefore, a congested disk. It matters little whether the cause of the congestion is seated in the brain, or whether it is local, as in neuritis. The congestion once produced is very apt to be increased by what Gräfe has called the "multiplying action" of the sclerotic ring, which, closely embracing the nerve on all sides, acts as a constricting cord around it. It can be readily understood, therefore, that in cases where exudation or effusion has taken place into the nerve, an enormous pressure will be brought to bear upon it where it passes through the sclerotic ring.

I have not attempted as yet to answer the objection made to the use of the ophthalmoscope in medical cases, that it never reveals the existence of disease which has been unsuspected before. It is certainly true that the diagnosis in many cases of cerebral disease may be correctly made without it. But, even if this were always the case,—and I believe I shall be able to show that it is not,—it can hardly be advanced as a valid reason for never having recourse to it. Similar reasoning would deprive us of the aid of the stethoscope in those cases of disease of the heart or lungs in which the general symptoms are alone sufficient to enable us to arrive at a correct conclusion. I have intimated that the ophthalmoscope enables us to detect disease which would escape discovery without its use; and I shall now bring forward, as evidence in support of this position, a case which I found in the women's medical ward of the Pennsylvania Hospital when I took charge of it on the 1st of November of last year. I shall illustrate this paper almost exclusively by the histories of patients who have been under my care during the last few months.

Case I.—Catherine C. was admitted into the medical wards of the Pennsylvania Hospital on October 12, 1874. She is an American by birth, but of Irish descent. She is 42 years of age, single, and a sempstress by occupation.

The patient's history, which was obtained shortly after her admission, is as follows. She has always had good health up to within a year, when she took cold, accompanied by great difficulty of breathing through the nose. At this time she suffered also from what she called neuralgic pains in the forehead; although it is probable these were really caused by the extension of the catarrh into the frontal sinuses. There was also pain at the vertex, but in all other respects she was perfectly well.

In June last she began to lose her hearing, and she states—but this is believed to be incorrect—that in the course of a few weeks she became absolutely deaf. Later symptoms were tinnitus aurium, unsteadiness of gait, pains in the limbs, impairment of sensation in the legs, vertigo, and occasional attacks of nausea. She has never had any loss of power in the limbs, and never any muscular trembling.

On the 1st of November, when I took charge of her, the following additional notes were taken:

The patient has a tendency, when walking, to fall forward and to the right, and on several occasions has actually fallen. Attacks of vertigo also occur in the erect position, and these are almost sure to be induced if she closes her eyes. She is, however, entirely free from them while in bed. She complains bitterly of the pain in her head; this is generally referred to the vertex, but sometimes to the forehead immediately above the eyes. Another annoying symptom is noise in the head. This she compares to the sound made by an engine in letting off steam. It is paroxysmal, being most intense in the morning upon first getting up, and being increased by any cause which brings on the vertigo. She occasionally suffers from nausea, but never vomits. There is no loss of power in the limbs, no paralysis of any of the cranial nerves, and, at present, no disturbance of sensibility. She is deaf, but not absolutely so, and, moreover, can hear better at some times than at others; the deafness being greatest when the vertigo, pain, and noise in the head are most distressing. She says she can hear me better than the resident and other gentlemen who accompany me in my visits to the

hospital;* and such appears to be the fact. To make her hear at all, it is necessary for the speaker to stand in front of her, which enables her to watch his lips closely. No evidence of thoracic or abdominal disease can be detected, and her appearance when seated does not indicate the existence of serious disease. Temperature, pulse, and respiration normal. She states that she applied some time ago for relief from her deafness to a prominent aurist of this city, who punctured the membrana tympani of the left ear, but that no improvement to her hearing resulted from the operation. Her gait is so unsteady, in consequence of the vertigo, that she was thought by at least one physician who saw her before she came under my care to be suffering from locomotor ataxia. But the unsteadiness evidently does not depend upon a paralysis of the co-ordinating power. No history of a syphilitic infection can be obtained, nor is there any reason to suspect it.

November 11.—Dr. Bertolet was kind enough, at my request, to make an examination of the patient's ears, from which it was discovered that there was slight retraction of the membrana tympani on both sides, but no perforation was detected. The Eustachian tubes are pervious.

November 13.—An ophthalmoscopic examination of the eyes was made to-day, and with the following results:

Right eye.—Outline of disk indistinct; on inner side they cannot be made out at all. Veins enlarged and tortuous, curving slightly as they pass over margins of disk, which is prominent.

Left eye.—Changes more marked. Outline of disk, which is more prominent than that of other eye, obliterated. Veins much enlarged, and curved at margin of disk, which is redder than normal; vessels not usually seen being distinctly visible towards its outer side.

December 10.—There has been a marked improvement in the patient's health since her admission into the hospital. Attacks of vertigo, however, although less frequent than before, still occasionally occur; but she considers herself better, and seems to hope that she will eventually get well. The ophthalmoscopic appearances are, moreover, less marked. She uses convex glasses when reading or sewing, but did not complain of any defect of vision before the examination of the eyes. The treatment consisted at first in the administration of tonics, which were replaced, after I took charge of the case, by the iodide of potassium in ten-grain doses three times a day.

The examination of the urine, which has been repeatedly made since her admission, furnishes only negative results.

This patient, previously to coming under my care, was believed to be suffering from progressive locomotor ataxia. The association of vertigo, headache, and noises in the head, with deafness, suggested to Dr. Bertolet, who happened to be in the ward very shortly after I took charge of it, the possibility of the existence of Ménière's disease; but if this pathological condition is really present it is not sufficient to explain by itself the choking of the disk, which I believe is caused by some interference with the flow of blood within the cranial cavity. None of the cranial nerves are paralyzed in this case, and all the symptoms except the choking of the disk could be referred to Ménière's disease, the principal pathological lesion in which is believed to be an effusion into the semicircular canals. Dr. Knapp has stated

* This is probably due to the fact that, as was first pointed out by Dr. Knapp (Archives of Ophthalmology and Otology, vol. ii. No. 1, p. 204), certain notes are better heard than others by patients suffering from Ménière's disease.

his conviction, in an able article in his *Journal of Ophthalmology*, that there is, in addition to this, a morbid condition of the cochlea. But, unfortunately, these are mere hypotheses, unsustained fully, as yet, by post-mortem examinations. I cannot find, moreover, the records of many ophthalmoscopic examinations in this condition, and it may, therefore, possibly turn out that the appearances of the eye, which I am now inclined to look upon as peculiar, are not unusual. At all events, there is in the case a lesion different from that which is generally supposed to exist in Ménière's disease, which I think could have been discovered only by the ophthalmoscope. Its discovery has made me more cautious in my prognosis, and has induced me to change the plan of treatment I had at first adopted.

It is in the early stage of cerebral disease that I believe the ophthalmoscope will be found most useful. In illustration of what I mean, I will refer to a case which came under my observation a few years ago, and in which violent supra-orbital neuralgia was the only prominent symptom. The various remedies usually prescribed in this disease failed to give the slightest relief from pain. No suspicion of syphilis appears to have been entertained at any time while the patient was in the hospital, and nothing in her history indicated the existence of this disease; consequently, no specific treatment was adopted. A year later, she returned to the ward paralyzed on one side, when it was accidentally discovered that she was the subject of constitutional syphilis. There can be little doubt that had an ophthalmoscopic examination been made when she was first admitted such an alteration in the disks would have been discovered as would have enabled us to recognize the presence of serious organic disease of the brain, and perhaps to have averted the accident which subsequently occurred. This, it may be said, is a mere assertion; but it is one which my experience, strengthened as it is by that of others, justifies me in making. We have, therefore, in the ophthalmoscope a valuable means of distinguishing organic from merely functional diseases, and of detecting the former at a time when a well-directed treatment is most likely to result in a restoration to health. It is at precisely the corresponding stage of pulmonary or cardiac disease that the stethoscope renders us the most efficient service.

The next case I shall introduce illustrates to some extent the value of an early ophthalmoscopic examination where there is a doubt as to the existence of inflammation of the meninges. The patient, a young colored woman, was unquestionably suffering, at the time I first saw her, from spinal meningitis, but, although some of the symptoms indicated that the inflammation had extended up into the cranial cavity, this was not positively ascertained until after the examination of the eye. At the time of writing, she presents absolutely no cerebral symptoms; but the persistence of the choked disk when taken in connection with the history of the case would reveal its nature to any one conversant with the use of the ophthalmoscope.

It is only proper to add that she would hardly

put her physician on the right track by complaining of any defect of vision, as she was unaware of its existence until her attention was called to it by my questions.

Case II.—Ellen C., æt. 18; single; born in Virginia; colored; was admitted into the medical wards of the Pennsylvania Hospital, October 25, 1874.

The patient's health, previous to the present attack of illness, has always been good, and she has no hereditary predisposition to disease. Two weeks before admission, after having been exposed to cold, she had a chill, followed by headache, diarrhœa, and pains in the lumbar region. She appeared to have had at this time some cutaneous hyperæsthesia, and also distressing pains in her arms and legs, but more particularly in the latter. These, which she attributed to rheumatism, were followed a few days later by great tenderness on pressure along the spine. This was a very marked symptom, pain being caused whenever she lay upon her back. She has suffered pretty constantly from headache, but it has, fortunately, been of only moderate intensity and dull in character.

On admission, the patient had fever, furred tongue, and a somewhat tympanitic abdomen; she had pain, with rigidity at the nape of the neck, and general tenderness upon pressure along the spine. There was decided retraction of the head, and some stiffness of the jaws. The movement of the arms or legs gave rise to a good deal of pain. There was also apparent loss of power in them. She complained of a "painful feeling" in the eyes, and of some tinnitus aurium, but her sense of hearing was unimpaired.

On November 1, the patient came under my care, when the following notes were made: "The retraction of the head still continues, and an attempt to raise it from the pillow gives rise to much pain. By persisting in the attempt not only the head will be lifted, but the shoulders also. Tenderness along the spine and pain on motion are still complained of, as is also headache. This, however, has diminished in intensity, and is now no longer constant. The tongue is moist, but slightly furred, the bowels are constipated, the appetite is poor, the grip of both hands feeble, especially that of the right side. She does not vomit, and she can move her legs much more freely than when admitted. There is some fever present.* The pulse and respiration are both more frequent than normal, but only moderately so."

November 18.—There has been a marked improvement in all the symptoms. Although she is still indisposed to move her legs when asked to do so, she has been seen on at least two occasions to leave her bed,—once to shut the door of the ward, and once to look out of the window at a passing procession. She is able to move her head freely, and can now open her mouth without difficulty. There has been at no time either retention or incontinence of urine, and at all times perfect control over the sphincter ani. A slight convergent strabismus on the right side was, however, noticed to-day for the first time, and an ophthalmoscopic examination of the eye showed that there was choking of the disks.

November 26.—Patient sitting up to-day for the first time. A slight ptosis on the right side is observed, together with a good deal of trembling of the orbicularis on both sides. Shortly after date of last note she told us she saw double; but this appears to be no longer the case. She walks moderately well, but staggers a little, this being apparently due to her want of strength rather than to paralysis. She complains a little, when

* The thermometer indicated a temperature of 102° on the evening of her admission, and one of 101° on the day following her admission. Since then her temperature has never been above 100° in the evening and 99° in the morning.

asked, of dimness of vision, but she is able to see well enough to do plain sewing.

November 30.—A close examination of the eyes shows that, in addition to the slight ptosis, the right eye cannot be moved as freely upwards as the left.

December 11.—Improvement continues. An ophthalmoscopic examination was made to-day, and with the following results: left eye, disk prominent, but a physiological cupping can still be seen; outline very indistinct on outer side; the vessels covered in places by exudation; the veins swollen and tortuous. Right eye, the same description will answer, but the changes are less marked. Patient's temperature is now normal, but it continued slightly elevated until the 29th ult., being, usually, 99° in the morning, and 99.5° in the evening, for the last three weeks. The treatment consisted at first in the administration of quinia, gr. xx daily, with a small quantity of opium. When I took charge of the case, I gave, in addition to these, ten grains of iodide of potassium. Believing that a dilated condition of the vessels of the membranes had been left by the inflammation, I replaced the latter on November 19 by thirty minims of the fluid extract of ergot, which was continued for two weeks, after which I resumed the administration of the iodide.

The next case which I shall report is one in which the ophthalmoscope simply confirmed the diagnosis which was made before it was used. The loss of the vomer and the presence on the face of cicatrices left by a previous eruption establish the fact, in spite of the patient's assertions to the contrary, that she is suffering from constitutional syphilis, while the headache, facial paralysis, and convergent strabismus, which were all present at one time, render it certain that she has a gummatous tumor of the brain, so situated as to press upon the sixth and seventh nerves of the right side.

The absence in the fourth case of any marked changes in the fundus of the eye renders the existence of a cerebral tumor, or of any other disease usually accompanied by choking of the disk, more than doubtful. There is probably present in this case an atheromatous condition of the small arteries of the brain, and, possibly, commencing sclerosis,—an opinion which is confirmed by the history, and by the facts that there is disease at the aortic orifice and that the radial arteries are hard and unyielding.

Case III.—Mary W., æt. 32, married; Irish; a house-keeper; was admitted into the medical wards of the Pennsylvania Hospital, October 9, 1874.

The patient's history previous to her admission is substantially as follows. She has been married ten years, but has never borne children. She states that her husband is and has always been a perfectly healthy man, and she stoutly denies the possibility of ever having had venereal disease. Her own health was good until two years ago, when, after taking cold, she began to suffer from a nasal discharge, which has persisted up to the present time. The discharge was thin and "natural" at first, but afterwards became thick and offensive, but she is not aware that any bone ever came away. About a year ago, she was seized with pains in the temples and forehead. These have continued until the present time, though worse at some times than at others. She has also had a good deal of tenderness of the scalp in the painful regions. Other symptoms from which she has suffered are vertigo, dimness of vision, and slight deafness on the right side.

On admission, the patient complained of pains in

the temples and forehead, and soreness of the scalp in those regions. She was pale, was without appetite, and in a very prostrate condition. Upon examination, it was found that the septum of the nose had disappeared. She had a peculiar expression, due partly to flattening of the nose from this loss of the vomer.

November 1.—On the 23d ultimo it was noticed for the first time that her face was drawn slightly to the left, and that her tongue, when protruded, was deflected towards the right side. The pain in the head still continues; it is described as sharp and shooting in character; it never extends to the occiput. She has vertigo, especially after any unusual movement; slight convergent strabismus of right eye, dimness of vision, but no diplopia. The facial paralysis still persists, and so does the deafness, but they are both slight in degree, no deviation of the palate being detected. There is slight loss of power in the right arm, but no diminution of sensation in any part of the body.

The cicatrices left by an eruption evidently rupial in character are plainly seen upon the forehead.

November 21.—Headache persists, in spite of the use of the bromide of potassium in large doses. An ophthalmoscopic examination of the eyes showed optic neuritis, with hemorrhage in the retina.

December 3.—Patient has had an acute attack of pleurisy. It ran its course without effusion, and it has left her, apparently, in very much the same condition as before.

December 11.—The ophthalmoscopic examination was repeated to-day, with the result of showing a slight improvement in the condition of the eyes. The appearances of the left eye, which is the most diseased, are briefly as follows. Disk prominent, veins enlarged and tortuous, outline of disk indistinct, but can be made out. Redness of disk less than when first examination was made. Hemorrhagic spot just above disk, and one near macula, but these are fading. Numerous white spots on retina, indicating probably the seat of former hemorrhages.

The patient's treatment at first consisted in the use of iodide of potassium, ten grains, with a small quantity of the bichloride of mercury (gr. one-twelfth), three times a day. In consequence of the severity of the headache, the dose of the iodide was increased to twenty grains thrice daily, while that of the bichloride was diminished to one-twenty-fourth of a grain. Under this treatment a rapid diminution in the intensity of this symptom has taken place, while there is some improvement in the other symptoms. The facial paralysis is much more marked on some days than on others, but it is never entirely absent. The patient's general health has also improved, in spite of the administration of the large doses of iodide of potassium, which has given rise to a pustular eruption principally upon the back. During the attack of pleurisy she took Niemeyer's pills, in addition to the medicines just referred to, it being thought imprudent to intermit the specific treatment.

Case IV.—Ann T., æt. 65; born in Ireland, but a resident of this country for thirty-seven years; single, and a domestic servant by occupation; was admitted into the medical wards of the Pennsylvania Hospital, May 29, 1874.

The patient presents a good family history, and enjoyed fair health, with the exception of occasional attacks of giddiness, until about three and a half years before her admission, when she was suddenly seized with vertigo without loss of consciousness. Upon recovering from this, she found she had incomplete paralysis of the left arm and leg. She states that she did not recover the use of these limbs for two years, and was unable during this period to do any work for her support. About a year and a half ago she was under

treatment in this hospital for vertigo, and "bad feelings" at the back of the head; she left improved, but not entirely relieved of the symptoms. One week before her present admission, she was suddenly taken, while lying in bed, with intense pain in the right arm and leg, accompanied by spasm of all the muscles of the right side. The spasm lasted three or four days, and was followed by partial paralysis of the right arm and leg. She has never had any loss of memory for words, and never any impairment of sensation in the limbs until after her admission. When admitted she was scarcely able to move either the right arm or leg, and had to be carried into the ward. She also suffered in a great degree from restlessness and insomnia. Her urine was found to be acid, to have a specific gravity 1016, and to be free from albumen.

November 1.—The patient is pale and worn-looking. There is loss of power in the right leg and arm, but she is able to use both to a certain degree; there is also marked general tremor, which is increased during voluntary movements. There is no trembling of the head when she walks, no nystagmus, and no scanning of the words when she speaks, as is said to occur in the condition described by M. Charcot under the name "*sclérose en plaques disséminées*." She still suffers a good deal from vertigo, and occasionally from headache. The examination of the heart shows that its action is feeble, and that there is a systolic murmur at the right base followed by an indistinct second sound. There is no constipation, and no paralysis of the bladder or rectum. An ophthalmoscopic examination does not reveal the existence of any actual lesion, but the disks are not so well defined as usual, and present rather a "dirty" appearance.

It is hardly necessary to recapitulate the treatment employed in this case, as it has been various, and seems to have exercised in no degree a controlling influence over the malady.

In addition to these cases I will refer to two others which were under my care last winter, and which are fully reported in the *Philadelphia Medical Times* for January 17, 1874.

In one of these—Case I., in the communication just alluded to—there was dilatation of the right pupil, convergent strabismus on both sides, headache, vertigo, loss of power, and a diminution of sensation. The ophthalmoscope revealed the presence of marked optic neuritis and of some retinal changes. Under the use of the iodide of potassium there was some improvement in the patient's condition. The symptoms here were attributed to lead-poisoning, the patient having been in the habit for some time previously of using white lead as a cosmetic.

In the second case the patient was discovered to have made the same use of lead. At first colic was the only symptom of poisoning, but eleven days after her admission she had, without any premonition, an epileptiform convulsion. This was followed by a second in about sixteen hours, and by a third five hours later. A fourth took place three hours after the third, and was fatal. There was nothing previously to the occurrence of the convulsions to draw attention to the eyes, or indeed to the brain, and consequently no ophthalmoscopic examination was made until just before death, when, however, marked changes in the fundus of the eyes were discovered. There can be no doubt that had such an examination been made immediately after the admission of the patient we should have been better

prepared for the severe cerebral symptoms which subsequently supervened, and which I confess I was at first disposed to look upon as a manifestation of an hysterical diathesis.

Before concluding this paper, which has outgrown its intended length, I shall refer to a recent paper by Annuske,* to show the frequency with which alterations in the disk accompany cerebral tumors. This distinguished observer has collected two hundred and seventy-six cases of cerebral tumors in which the post-mortem examination fully confirmed the diagnosis made during the life of the patient. In only forty-eight is there any record of an ophthalmoscopic examination, and in one of these the result of the examination is not given. In the remaining forty-seven cases, white atrophy occurred eight times, neuritis of one side only once, and double neuritis thirty-three times.

Atrophy, he goes on to say, is generally the result of previous neuritis, although he admits the possibility that simple atrophy, from intra-cranial growth, may occur; but this has never been demonstrated. He therefore regards optic neuritis as a constant symptom of cerebral tumors, and as a rule it is a very early one. "Its occurrence with other intra-cranial affections cannot be considered to greatly invalidate its importance as a symptom of tumor. On the one hand the other intra-cranial affections which are likely to give rise to neuritis can (exceptional cases aside) only temporarily cause error in diagnosis, since their other symptoms characterize them as acute diseases, while tumors, though often exciting acute symptoms for a time, follow in general a chronic course. On the other hand, such intra-cranial affections as are likely to be confounded with tumors from their general symptoms and course (chronic encephalitis, softening, and cerebral abscess) never excite optic neuritis." "Reich (*Monatsbl. f. Augenheilk.*, June and July, 1874)† gives further statistics of intra-cranial growths, which confirm, in the main, those of Annuske, though they make the proportion of cases in which optic neuritis is wanting somewhat greater. Of eighty-six cases not included in Annuske's tables, there was ophthalmoscopic examination in forty-five. In forty-one of these there was double optic neuritis, or atrophy ex neuritide; in one, neuritis of one side; in three, no change in the disks."

Taking all the cases given by both writers (92), there was in 95.65 per cent. optic neuritis or atrophy ex neuritide; in 93.5 per cent., double; in 2.15 per cent., single; in 4.35 per cent., no ophthalmoscopic change.

I could add other cases to those just detailed in support of the position I have taken in regard to the ophthalmoscope, but the records of cases are very apt to be wearisome, and I have therefore preferred to report in full only those cases which were under treatment in the ward when I took charge of it, and in which no previous examination of the eye had been made. I think I have shown that the ophthalmoscope materially assisted me in arriving at a

* Boston Medical and Surgical Journal, November 5, 1874, from Gräfe's Archiv, xix. 3.

† Boston Medical and Surgical Journal, November 5, 1874.

correct conclusion in some of them. A point to which it may be well to draw attention is that in none of these cases was there complaint of much impairment in vision. Had this been the case, the patients would probably have sought relief at a dispensary for diseases of the eye. In this way the ophthalmologist and the general practitioner, unless they work together, will see very different classes of patients.

PURPURA HÆMORRHAGICA IN A CHILD SUCCESSFULLY TREATED BY THE HYPODERMIC USE OF ERGOTIN.

Read before the Northern Medical Association.

BY ANDREW K. MINICH, M.D.

THE child, Philip G., aged 7 years, complained of feeling unwell a few weeks before I was hastily summoned. He is the son of German parents, both of whom have always enjoyed good health. His mode of life and the hygienic conditions have always been good, so that his disease was not due to a want of proper food, air, clothing, etc.

I found the family in great alarm, and, as I looked at the boy, pale as death, with blood upon his bed and clothing, and blood streaming from both nostrils and issuing in large quantities from his mouth, I felt they had abundant cause. It seemed as though the child was a leaky blood-vessel: blood was issuing everywhere. It passed with his urine, it oozed from the lining of his mouth, it infiltrated the parotid glands until they were distended almost to bursting, it pushed its way to the skin, as shown by numerous small ecchymoses and about twelve large, purple, irregular blotches upon his body, about the size of a peach-leaf. They were more numerous upon his arms and legs.

The attack came on suddenly, though, from the previous history, the bleeding was probably but the last symptom of a disease which had its beginning when the child first began to complain.

When I first saw him, his skin was cool and dry, save his forehead, upon which sweat-drops stood out. Pulse 108, temperature $97\frac{1}{2}^{\circ}$.

One grain of ergotin was at once injected under the skin of the arm. Sponging with infusion of oak-bark was also ordered. Four hours afterwards (evening) the profuse vomiting of blood had entirely ceased, but the blood was still issuing from one nostril. One grain of ergotin again administered hypodermically. Pulse now 108, temperature 98° .

The next morning, bleeding had entirely ceased. Urine was still dark-colored. Rubbing of the nose started blood from one nostril. Gave another injection. Sponging continued. Pulse 106, temperature $98\frac{1}{2}^{\circ}$. The small spots have almost entirely disappeared. Half a fluidrachm of fluid extract of ergot, five drops of dilute sulphuric acid, and four drops of deodorized tincture of opium were ordered to be given every two hours.

Morning of third day.—Hemorrhage entirely ceased. Urine muddy, but free, apparently, from blood. Parotids very much swollen. Child had slept well during the night, is very feeble. Pulse 108, temperature $98\frac{1}{2}^{\circ}$. Large spots are beginning to fade. Medicine to be given every four hours. Also ordered wine, and a pill consisting of quinine, iron, and strychnia. His bowels moved to-day, for the first time since the attack. The passage was quite profuse, consisting of dark, hard, bloody lumps. Unfortunately, none of the bloody urine could be collected, as it was passed unconsciously.

The following is the report which Dr. John Haynes kindly sent me from a specimen obtained upon the fourth day: "Urine muddy; large white sediment, com-

posed of crystals of uric acid and amorphous phosphates. Specific gravity 1026. No albumen; no pus."

Fifth day.—Child is doing well: eats well, sleeps well, feels well, looks well. Ergot discontinued. Tonic pill still administered.

Seventh day.—The child is up and playing about the room. He is gaining in strength, color again returning to his cheeks. The large purple spots have changed to a very faint greenish-yellow.

Remarks.—This case is one of interest in more ways than one. Its rarity, as occurring in a child, is an interesting feature. Many practitioners have never met a case. Dr. West, in an extensive practice among children, saw, I believe, but six cases. Dr. John Forsyth Meigs, enjoying, without doubt, the largest practice in this city in this special field, in answer to a note of inquiry informs me that he remembers but two well-marked cases in patients under ten years of age. In these, there was hemorrhage from the nasal passages, gums, and kidneys. Both cases ended in recovery. He also states that he remembers, indistinctly, several other cases, but cannot specify about them.

Recently, three cases, to my knowledge, have occurred in the upper section of the city. One was reported in the *Philadelphia Medical Times* by Dr. Boissot, in which transfusion was instituted and the child thereby saved. Another occurred in the practice of Dr. William Bennet, and was reported at a meeting of the Episcopal Hospital Club. His patient, who died, was an infant at the breast. Blood issued from its mouth, nose, and bowels. The purple spots or blotches were also well marked. The other is the case which has called forth this paper.

In speaking to some physicians about cases of this character and their treatment, a number suggested vegetable diet. Evidently they confounded this disease with scurvy. There is a broad line separating the two. Scurvy comes on slowly, purpura very often suddenly. Scurvy has for its cause a want of a variety of diet; purpura is independent of this. Scurvy has its chief and constant symptom in a softness and sponginess of the gums, with blood oozing from its mucous covering. Purpura has not, and the hemorrhage is very often general. Scurvy will be cured by correcting the diet. Purpura will be very little influenced by this alone.

Purpura is generic in its signification, and one must distinguish between its species or varieties. *Purpura urticans*, or the nettle-rash purpura, commences with the formation of elevations like the eruption of nettle-rash, though without the accompanying irritation of urticaria.

Purpura senilis occurs, as its name implies, in the aged, more frequently in women. It is oftener seen upon the arms than elsewhere. It is probably due to severe local irritation, and usually lasts for a long time,—sometimes for years.

Purpura simplex is characterized by the appearance of small purple spots, and is associated with great lassitude and languor and general symptoms of mal-nutrition.

These three forms of purpura are not considered dangerous. The fourth variety is the *purpura hæmorrhagica*, the symptoms of which were offered in

this case. Unlike the other members of this group, it must always be considered a dangerous disease, especially in children. Patients may die from exhaustion, from either external or internal hemorrhages.

Its pathology is still unsettled. Some regard it as a fatty degeneration of the capillary vessels; others believe that the fault exists in the blood.

In Dr. Bennet's case, fatty cells were found in abundance in the liver and kidney tissues. A specimen of blood obtained from my case the seventh day was sent to Dr. Morris Longstreth, which he kindly examined. This is his note: "The blood was quite dry when I arrived home. There was nothing found, however, after treatment, to justify me in pronouncing the blood, from its microscopical appearance, other than normal. It clotted firmly, and corpuscles were seen separated into masses. There was no excess of white corpuscles that I could detect." I would here state that in the vomited blood small clots existed.

The greater interest of the present case is in connection with its treatment. It was formerly the practice to rely upon oil of turpentine, which was, and is still, highly lauded. How it acts we do not know. Since the pathology of purpura is unknown, its treatment is, of course, experimental. We treat a symptom when the patient's life or comfort demands it, no matter what processes underlie it. This is pre-eminently so in purpura. Though hemorrhage may not be the disease, it is the wave upon which the patient's life is borne away, and it behooves us by the bedside to lay aside thoughts concerning the ultimate cause of the flow, and adopt measures to stem the tide.

We have (thanks to the deeply-searching spirit of modern investigations on the physiological action of drugs) one remedy upon which we can assuredly rely in this disease. I refer to ergot. The experiments of Holmes, Wernich, Kersch, and Vogt upon animals confirmed the theory advanced by Courant in 1827, that ergot produces contraction of the blood-vessels. In man, Nicol and Mossop have observed with the ophthalmoscope the contraction of the retinal vessels after the administration of ergot.

Since the publication of their experiments, ergot has been extensively used, both internally and hypodermically, to arrest bleeding, and, I believe, with almost uniform good results.

I thought that I was the first to employ ergotin hypodermically in purpura, but a medical friend has called my attention to a case reported in the second volume of the *British Medical Journal* for 1874, p. 304. Dr. W. L. Lane there details the history of a girl aged 16, convalescing from typhoid fever, in whom purpura hæmorrhagica manifested itself. He injected one grain of an extract of ergot, which had, he states, the effect of completely arresting the flow of blood.

What is the relation between ergot and purpura hæmorrhagica? We know that purpura is not a self-limiting disease, like the continued fevers, which will recover simply through nature again "asserting herself." Its tendency is towards

death. It is not, so far as I know, associated with fever. It may exist incidentally. The temperature of our case was below the normal, being $97\frac{1}{2}^{\circ}$ at the outbreak, and rose gradually as convalescence advanced. If the disease is in the blood, if it lacks the proper proportion of constituents, why will ergot cure a case? What restorative power can ergot have upon the blood? None.

If purpura is a fatty degeneration of the capillaries, why will one or two injections of ergotin cure? What influence can ergot have upon the formation of fat-cells? We do not give ergot in fatty degeneration of the heart, liver, or any other viscus. Ergot produces *vaso-motor spasm*. The capillaries contract by this stimulation of the vaso-motor nerves. May not purpura hæmorrhagica belong to the neuroses? May it not be a *vaso-motor paralysis*? Such a condition would permit the capillaries to dilate, widening the interstices in the tissues of the capillary walls, thus forming channels for the blood to ooze through. Since theory alone has had to deal with the nature of this disease, this seems to me a more rational view. Regarding purpura hæmorrhagica, then, as a *vaso-motor paralysis*, we have explained to us somewhat satisfactorily how it is that ergot will cure this affection,—cure it by promptly closing up the ten thousand avenues through which the patient's blood and life are ebbing away.

2228 NORTH FRONT STREET.

NOTES OF HOSPITAL PRACTICE.

UNIVERSITY HOSPITAL.

Abstract of a clinical lecture on Diseases of the Skin, delivered at the University Hospital, April 13, 1875, by Louis A. Duhring, M.D., Clinical Professor of Diseases of the Skin.

Reported by ARTHUR VAN HARLINGEN, Chief of the Skin Clinic.

ECZEMA COMPLICATED WITH RHEUMATISM AND FOLLOWED BY SEBORRHOEA.

C., MALE, 22 years of age, had been under treatment in the ward for some time with generalized eczema, assuming on the body the characters of the erythematous form of the disease, while on the scalp the pustular form prevailed. The affection was of a peculiarly violent type, and had been under treatment for about two years. Some time after his admission to the hospital, the eczematous affection was observed to disappear suddenly and almost completely.

Some trouble was supposed, and, as the event proved, with reason, to be impending, for a few days later an attack of acute rheumatism supervened, which lasted some weeks. During this time the eczema scarcely showed itself; no attention was paid to it. Recently, however, the patient has recovered from his rheumatism, and the skin-affection again demanded treatment. While the patient was passing around for inspection, Dr. Duhring drew attention to the condition of the scalp. Eczema was no longer present, but in its place a new affection,—seborrhœa. The scalp is not, it may be observed, red and inflamed, but pale. It is covered with thick, pearly-gray scales, not so fine and dry as those of eczema, but larger, and attached more or less closely to the hairs. If some of these scales are picked off, the skin underneath will be seen to have a peculiar moist look, and a leaden color which is quite characteristic.

The present treatment will be as follows: The scalp is to be cleansed thoroughly morning and evening by the use of *sapo viridis*, the well-known "green soap," which contains an excess of potassa. After this has been thoroughly washed out, the following ointment is to be well worked into the scalp in small quantities, avoiding so far as is possible smearing the hair:

R Hydrarg. oxid. rub., gr. v;
Glycerinæ, ℥i;
Adipis, ℥i.—M.

Under this treatment the patient rapidly recovered, and was discharged from the hospital.

MILIARIA.

A. B., child six months of age, presents an eruption confined to the back and chest, consisting of minute pin-point and millet-seed sized vesicles, upon an inflamed base. The vesicles are in all stages of formation; some contain a clear, others a puriform fluid. They are very numerous, scattered over the surface, not grouped, but discrete, and showing no tendency either to coalesce or to rupture. They present a transparent, yellowish appearance, surrounded by a hyperæmic condition of the skin. In addition to the eruption the child is seen to be very much bundled up in clothes, and in a state of perspiration.

The affection before the class, Dr. Duhring said, was one involving the sweat-glands; a simple disorder produced by excessive and disordered action of these organs, and known as *miliaria rubra*. There are two kinds of miliaria; one, unattended with inflammatory or hyperæmic symptoms, and known as *miliaria crystallina*, in this country also as sudamina; the other, accompanied by marked signs of glandular and cutaneous disturbances, *miliaria rubra*. Miliaria rubra is quite a common affection in children, and its treatment is simple. In order to assuage the heat of the skin, dusting with powdered starch may be practised, and the vesicles may be broken open and destroyed by rubbing with soap and water.

XANTHOMA.

M. L., a dark-complexioned woman of 45, apparently in fair health, but with some eczema of the fingers. The skin of the face is dusky and rather oily-looking, but perfectly healthy, excepting the eyelids. On the right lower lid is a patch of diseased skin about one-fourth of an inch wide and half an inch long, extending upwards and inwards, and gradually fading away towards the inner canthus. This patch is of a dark canary yellow, very slightly thickened, so that it still allows the finer wrinkles of the skin to be seen in it, and quite level with the surface. On the left upper eyelids three patches of a similar nature can be seen; these are roundish and slightly raised above the surface. They give no pain, and the patient was not aware of their existence until her attention was called to them. They could not have been of more than a few months' duration.

This, Dr. Duhring remarked, was a case of a very rare disease,—*xanthoma planum*. Having once seen it, one is not likely to forget it, as the appearances are quite peculiar, and always about the same.

The affection usually occurs upon the eyelids, but is sometimes found on other parts of the body. Its situation is in the subcutaneous connective tissue, but very superficial. It looks as though it were sunk or inlaid in the skin. Xanthoma was formerly supposed to be connected in some way with disease of the liver, and to be caused by deposit of the biliary coloring-matters in the skin. It is now believed to be entirely unconnected with hepatic disturbance, and to be a simple hypertrophy of the connective tissue, with fatty metamorphosis.

TRANSLATIONS.

ARSENIC IN DIABETES MELLITUS.—Dr. Samuel v. Pap contributes to the *Wien. Med. Presse*, Nos. 13 and 14, the results of his experience in the treatment of diabetes, particularly as regards the use of arsenic in this affection. He finds that this remedy exercises a decided influence in diminishing the pathological excretion of sugar, whether this be due to excessive sugar-formation in the system or arrested metamorphosis of the normal sugar. In many cases the use of arsenic causes the sugar to disappear entirely from the urine; naturally, the various other symptoms of diabetes,—thirst, dryness in the mouth, increase in the amount of urine, weakness, etc. The favorable effect of arsenic is more noticeable in those lighter cases of diabetes where the sugar present in the urine does not rise above 4 per cent. The diminution or disappearance of the sugar takes place even while mixed diet is used, but at the same time it is advisable to use as little starchy food as possible. After the use of arsenic has been suspended, months may elapse before the diabetic condition again makes its appearance; nevertheless, the use of this remedy does not protect against relapse. No unpleasant effects are observed from the prolonged use of the arsenic; the appetite remains unaffected, and even, in many cases, is improved. As a contra-indication may be mentioned the highest grade of the disease with progressing pulmonary tuberculosis.

The arsenic was administered in the form of Fowler's solution, beginning with three drops in twenty-four hours, and gradually increasing the dose to twenty drops per diem. X.

TOXIC PRINCIPLE OF PUTREFIED BLOOD.—M. Feltz has injected into dogs certain quantities of putrefied blood which had been submitted to certain modifications, either by depriving it of gas or submitting it to the action of compressed air or oxygen. His conclusions are as follows: 1. Septicæmia may be developed in the dog by intra-venous injections of putrefied blood. 2. Long-continued currents of air passed over the blood and compressed air seem to have no action either upon the toxic qualities of the putrid blood or upon the infinitely minute bodies contained in it. 3. The blood, after having been oxygenated a long time by the contact or passage of this gas in a state of purity, seemed to become less toxic, and to differentiate itself from the original blood by a diminution of the movements of the vibrios and spiroæ. The blood, deprived of gas and left in a vacuum for a certain time, appeared also to lose its toxic power. The various minute organisms lost their activity, but did not die.

The toxic principle, according to M. Feltz, is apparently a gas.—*Bull. Gén. de Thérap.*, March 30. X.

ABLATION OF THE BREAST BY THE ELASTIC LIGATURE.—M. Périer had under his care recently, at the Salpêtrière, an old woman suffering from a tumor of the breast (diagnosed cysto-sarcoma).

This tumor, the size of the fist, mobile and detached by its own weight from the surrounding tissues, was removed by the elastic ligature. The base of the tumor was surrounded by the ligature, the ends of which were then tied under long pins previously introduced. The tumor preserved a red color for a few days, then became blue, and finally fell off. Unfortunately, the patient died two months subsequent to the operation, of erysipelas of the face. The advantages of the operation are the avoidance of loss of blood, more rapid cicatrization than with the galvano-cautery, and the being able to do without anæsthetics.—*Bull. Gén. de Thérap.*, March 30. X.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MAY 8, 1875.

EDITORIAL.

ORAL SURGERY.

SOME months since, there were published in our columns certain editorials upon dentistry which gave rise to a good deal of angry private and semi-public criticism. As an example of much of this, we may be pardoned mentioning that a prominent member of the craft, whose sober opinion ought to be valuable, assured us in a public place, in the most solemn manner, and in the presence of numerous witnesses, that "the day will come when your children and grandchildren will point their fingers of shame at this and say, 'Father, or grandfather, did you write this?'" Finally, the editor of a usually dignified journal was betrayed into publishing an editorial of such a personal character that we could not at the time, consistently with our own self-respect, notice it, so that we let the matter drop. Our interest in the subject has, however, never been lost, and we have read with much pleasure the able debate upon dental education which is contained in the report just published of the special meeting in December of the New York Odontological Society. We have not space for even a fair abstract of this lengthy discussion, but desire to call attention to several points in it. In the first place, it fully establishes the truth of all that has been said in regard to the unworthiness of the dental profession, as it now stands, to rank as a branch of the medical fraternity. Indeed, it does more than substantiate our words.

James Truman, D.D.S., of this city, in the open-

ing address says that to-day "there are from eight to eleven thousand persons engaged in the practice of the profession [dentistry] who have not the degree [D.D.S.], and of whose general intelligence we have no means of knowing. It is very safe to assume that a large proportion are men whose attainments do not extend beyond the mere practical routine of mechanical operations, and a very large number are by no means experts in these directions. Generations must come and go before we can occupy the present favorable position of the medical profession." Later in his speech, Dr. Truman asserts that dentistry at the present time has no claim to be considered a specialty of medicine. Howsoever the dental profession may be divided on this point, we can assure Dr. Truman that the medical profession is singularly a unit in agreeing with him.

Broadly viewed, the gentlemen who took part in the debate were divided into two camps: those who argued that dentistry should exist as dentistry, and those who desired that it is or should be a specialty of medicine. We do not propose here to enter in any way into the discussion of what dentistry ought to be, but merely to point out that it is not at present a medical specialty.

In what seems to us the ablest speech made upon the occasion, Dr. Garretson, of this city, argued in favor of progress. He really expresses the whole gist of the relations between dentistry and medicine in the following sentence:

"Most decidedly am I, for one, in favor of the abolishment of the degree of D.D.S. One degree in medicine is enough; the greater covers the lesser, and includes it. A doctor in medicine possesses a title quite extensive enough in its signification to embrace any specialty that he may elect to practise; besides, it affords the only possible bond of brotherhood with the members of the profession at large. We may be specialists, but we can never be esteemed as doctors, in the desirable fulness of the term, until we replace the D.D.S. with the M.D."

Let editors write as they may, conventions debate, discuss, or pass resolutions as they please, one thing is certain: that D.D.S. is the badge of a partial culture, and that the medical profession never will stultify itself by recognizing as coequal or as a part of itself a profession to the highest positions in whose ranks such a degree is the only necessity for entrance. It may do very well for gentlemen who place only their medical degrees on their door-plates before the world to affirm in convention that they prize the D.D.S. above the M.D., but in doing so they only make themselves singular: they do not affect or reflect the general public opinion. Those

gentlemen who look upon dentistry as belonging to medicine should weigh well the words of Dr. Garretson. On behalf of the medical profession, we freely admit that many, it may be all, of the dentists who took part in the debate at the Odontological Society far exceed, in point of general, literary, scientific, and even in special medical culture, many of our physicians. But that does not affect the question. The medical profession is perfectly willing to admit dentists to its fraternity so soon as they become doctors of medicine, but never whilst they are merely doctors of dentistry. Really, the physicians are, in great part, indifferent in this matter; but just so soon as the universal law of the medical profession—that the specialist shall first be a general practitioner, and shall have no special degree—is complied with, the medical profession will at once assimilate this great new body.

The latter part of the following extract from the speech of Dr. Garretson has an application much beyond that which he made of it:

"It has come most plainly to exhibit itself, not only to ourselves, but as well to the community, that our field of labor does not correspond with our learning, our social position, nor, indeed, with pretensions necessarily associated with a title which we have arrogated to ourselves. We are very wrong in esteeming that in ill temper on the part of certain editors, or in crustiness of disposition on the part of other people, originate criticisms that some of us do not like to hear. The trouble is not exclusively with these; but these rather are as the voices which precede the whirlwind of public opinion; and not to give heed, is to exhibit little more discernment than the foolish ostrich, which, with head and eyes buried beneath the sand, esteems itself free of all danger."

CORRESPONDENCE:

NEW YORK, April 22, 1875.

PROF. SAYRE has lately performed his fifty-fifth and fifty-sixth hip-joint exsections,—both in the same week. The first was made in Brooklyn, in the presence of Prof. Gross and both the Pancoasts of Philadelphia, who chanced to be in town. The case was a desperate one, and ought really to have been operated on two years ago. Dr. Sayre first saw the child, who was seven years of age, about two months before the date of exsection, but had been unavoidably obliged to delay operating from time to time.

During March a profuse and obstinate diarrhoea had set in, and emaciation was now extreme; so that there seemed altogether a very slim chance of saving the little patient; which, indeed, could only possibly be done by operative interference. At the time of the operation he was almost *in articulo mortis*, and at one stage of the proceedings he ceased to breathe, and it

was thought that he was actually dead. Prof. Gross, however, who held the pulse, noticed that the heart did not altogether stop beating. The table was inclined (so as to depress the head) until the completion of the operation; the mouth was constantly moistened with ammonia, and finally the patient began to revive. The destruction of tissue in this case was very extensive.

Dr. Sayre at first thought the acetabulum was not perforated, but soon discovered that it was, and that the head of the femur, already detached, plugged up the large hole through it. When this was removed, an enormous quantity of pus gushed forth; which was exceedingly fetid, from its having been in such proximity to the sigmoid flexure of the colon. There were no less than three sinuses whose external orifices were above Poupart's ligament. We are happy to say that the child began to improve immediately after the operation, and is now doing exceedingly well; which goes to prove the truth of the remark that Dr. Sayre often makes, that his most hopeless cases often turn out the best in the end. He certainly could not wish for a more hopeless one than the above.

The second case was operated on at his clinic at Bellevue College, and on this occasion a patient on whom he had performed exsection of the hip-joint just two months before was presented to the class. The little fellow was certainly wonderfully improved, and the father said he had gained about ten pounds since the operation. He was now taken out of the "wire breeches," in which he had been kept ever since then, and it was found that the lower extremity of the affected side was already quite as long as the sound limb. A long steel splint, reaching just above the hip, was then applied, and the patient allowed to walk about freely.

The new case was a little girl of five, in whom the disease had existed for two years and had now reached the third stage. She was in much better condition than either of the other patients, being, in fact, quite fat. The acetabulum was not perforated. After the operation she was placed in the same apparatus which had just been "shed" by No. 54, as both children were of about the same height. This case is also doing well.

Since Prof. Sayre's unjust removal from the position of attending surgeon to the Bellevue Hospital last summer, his clinics at the college have been constantly increasing in interest and importance, and his material is now so abundant that he can never succeed in bringing before the class half the patients that present themselves. A very good idea of the number and variety of cases he *does* present, however, may be obtained from the verbatim report of one of his ordinary clinics, published in the *Philadelphia Medical Times* of April 10. After the publication of his clinical lecture on hip-joint disease in the Putnam's series, a number of gentlemen expressed their surprise that he should be able to get together on the same day three cases illustrating the three stages of the disease; but this was entirely an accidental occurrence, and is by no means uncommon at his clinics.

Among the more interesting clinics in New York is

that of Prof. Abram Jacobi, at the College of Physicians and Surgeons, for diseases of children. It is kept up through the year, and is almost always pretty well attended. At his last lecture, Wednesday, he presented a number of attractive cases, among which were the following:

1. *Cephalæmatoma*.—A child of five years had a bad fall five days ago. Two days later, the mother noticed a lump on the head. We now find in the region of the right parietal bone a large, fluctuating swelling, surrounded on all sides by a hard ridge. An inexperienced person might suppose from this that the bone was depressed beneath the soft tumor. There has not at any time, however, been any vomiting or other brain-symptom. This is precisely like the *cephalæmatomata* of newborn infants. The blood collects under the periosteum, forcing it away from the bone, and this is just as likely to occur after the simplest labors as after the most difficult. It is a characteristic of this affection that, on account of the peculiar formation and attachments of the periosteum, it cannot extend from one bone to another. The hard ridge around the edges is really necessary to the diagnosis of *cephalæmatoma*, and is due to the formation of new bone just at the point where the periosteum separates. No treatment is to be employed, as the blood will eventually be absorbed; though the parietal bone will remain permanently thickened. The great point is to keep the patient's head free from injury, applications of all kinds, and especially the interference of doctors.

2. *Bromide of potassium followed by an eruption*.—The child is three years of age. When eight months old, he fell from a height of four feet, and two weeks afterwards had a severe epileptiform convulsion. This was repeated every day up to last July, when he had an attack of scarlatina; after which he had no more fits until January. From that time to the 31st of March they occurred two or three times a week. At the latter date he was brought to the clinic, and fifteen grains of bromide of potassium three times a day were ordered. After this he had no more convulsions, but three or four days after commencing the medicine, a rash (probably urticaria) broke out. The dose of the bromide was afterwards diminished to twelve grains. We now notice well-marked eczema developed, particularly on the legs; and this is, no doubt, principally due to the child's scratching. The drug has produced no other toxic symptoms, the general health being excellent, and we shall, therefore, go on using it, since it seems to control the convulsions so admirably, at the same time treating the eczema as an ordinary case of that disease.

In this case, rachitis, which predisposes the skin, as well as the glandular tissues, to inflammation, has, no doubt, been the ultimate cause of the severity of the skin-disease. The mother says the child cut its upper central incisors before the lower ones, a fact which Prof. Jacobi has long claimed denotes premature ossification of the skull. He says he cannot claim priority in this matter, however, since he has recently read, in Dr.

Livingstone's last work, that in the province of Lunda, in Central Africa, the natives always destroy infants whose upper teeth protrude first, as they have found that they are apt to grow up idiots or epileptics.

3. *Rheumatic endocarditis followed by chorea minor*.—This child, between four and five years old, had a severe attack of pneumonia early in the winter, recovering about the 1st of January. She was then well till March, when she had a well-marked attack of acute articular rheumatism. There was also *endocarditis*, and auscultation revealed mitral insufficiency after the attack had passed. *Chorea minor*, as is not at all uncommon in these cases, also soon developed. She was put upon the tincture of the chloride of iron and digitalis, but, the chorea not being thus controlled, Fowler's solution was given in addition. Chloral at night, when necessary, to secure sleep. Under this treatment she is now improving as rapidly as we could expect.

4. *Scleroderma*.—The patient is eight or nine years of age, and the disease is of over two years' standing. It involves the trunk and both the lower extremities. There is marked atrophy of the right, particularly, whose measurements are scarcely more than half those of the left. An entire absence of connective tissue is noticeable, and there is also some shortening of the limb. There has been no œdema, so far as can be ascertained. This is certainly a remarkable case, and is especially interesting from the rarity of the disease. Meigs and Pepper have seen only one case in a child, and that was an acute attack in an infant suffering from *atelectasis pulmonum*. The person who accompanied the child said that a younger brother was also now similarly affected.

An interesting joint meeting of the city Public Health Association and the Dwelling Reform Association was recently held at the School of Mines, Columbia College, to consider the subject of improving the homes of the poor; and we trust it may be productive of much good, for there is certainly the most urgent need of reform in this matter. Dr. Stephen Smith, whose long connection with the Board of Health has rendered him perfectly familiar with the subject, read an excellent paper, in which he reviewed the crowded condition of this city in certain quarters, and suggested remedies for the evil. In three wards alone, over half a million of people lived, crowded into twenty-three thousand houses, so badly drained and ventilated that health and virtue were almost impossible. In London, companies bought outside lands, planned villages, and built cottages, the rent of which was received as purchase-money. Mr. Disraeli, who lately visited one of the villages of "The Artisans', Laborers', and General Dwellings Company," said that he was pleased and surprised at its success, and that it was, in part, a solution of a great social problem.

In Philadelphia there are several hundred co-operative associations. At the distance of three-quarters of an hour's ride from the State-House, a mechanic could now purchase for \$200 a lot 18 feet front by 90 feet deep, and could erect a house worth \$1000, by

simply paying about \$150 per annum to one of these societies. When the whole was paid, the ownership was transferred to him. This is certainly a wonderful contrast to the state of affairs in New York, where the laboring-man has to pay an exorbitant rent for two or three miserable rooms in a wretched tenement-house.

Dr. Smith said that, if proper measures were taken, communities like those of London and Philadelphia could be established along the lines of the Hudson River, Harlem, and New Haven Railroads, in an incredibly short period. Yet, however well such a plan might succeed, there would always be a city population left, and the remaining problem was, how to deal with them. He would, therefore, make the following suggestions: 1. Utilize all available waste room. In the first and second wards, now nearly deserted, there are empty buildings enough to accommodate about fourteen thousand people. 2. Improve existing tenements. In this the tenants' aid should be sought, after the plan of Miss Octavia Hill, in London, who, with money furnished by Mr. Ruskin, bought old tenements, and became herself the landlady. 3. Erect new and improved tenement-houses. This might be made a municipal reform, as in Glasgow.

At length, we believe, the commencements are over for the season. The last was that of the College of Pharmacy, whose graduates numbered thirty-eight; and on this occasion the students presented to the college, through Prof. Bradford, a fine painting of Dr. Chandler, Professor of Chemistry in that institution and in the Columbia School of Mines, and one of the most popular scientific men known to New York for a number of years.

During the past month, Prof. Doremus, who seems to enjoy particularly any occasion which brings him conspicuously before the public, has been giving a short course of brilliant lectures on "The Agreement between the Mosaic and Scientific Accounts of the Creation." These lectures were first delivered some years since, and have now been repeated, of course with the additions rendered necessary by the advance of science, at the request of a number of distinguished gentlemen.

The paper by Dr. Lautenbach in the last number of the *Times* proves a very appropriate contribution to our knowledge of the physiological action of conium, in view of the interest excited in the subject by the recent poisoning case in Brooklyn. Dr. A. N. Bell, who was one of the Coroner's jury in that case, is to read a paper in reference to it at the Medico-Legal Society to-night.

PERTINAX.

CASE OF INVERSIO UTERI OF TWO YEARS' STANDING (*N. Y. Med. Journal*, April).—Dr. B. F. Dawson reports a case of this kind, resulting from improper traction on the cord and placenta after labor, and lasting undiagnosed for nearly two years. Repeated attempts at manual reduction under ether, with injections of warm water between times, finally resulted successfully, and the patient returned to her home in the country six days later.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A T a conversational meeting, held Wednesday, February 24, 1875, at 8 o'clock P.M.,

PRESIDENT, DR. WILLIAM GOODELL, in the chair,

Dr. W. R. D. BLACKWOOD made some remarks on a case of delivery by abdominal section after the death of the mother, which he said had been incorrectly reported to this Society, and which had appeared in the *Philadelphia Medical Times* of February 6, 1875. The doctor alluded to two cases which occurred in his practice during his residence in the Southern States, in one of which the child was successfully delivered by Cæsarean section five minutes after the mother's death. In the other the child was delivered twenty minutes after the death of its mother, but it could not be resuscitated. He also referred to a case in the practice of a friend, in which, fifteen minutes after the death of the mother, the child was delivered and was dead. From all that he had been able to read upon the subject, it appears that the child cannot survive the death of its mother for a longer time than from five to fifteen minutes.

Dr. O. H. ALLIS mentioned a case that was related to him by a competent witness, where a woman died of tetanus almost at full term, and the foetal heart was heard to beat for five minutes. There was no attempt made to deliver her.

Dr. W. B. ATKINSON said he was called to meet Dr. Patterson in consultation in a case where the patient had just died after an attack of convulsions of about fifteen hours' duration. Delivery had been attempted with the forceps, and was finally accomplished by turning. Resuscitation was attempted, without success. He believed that he had observed rapid dilatation of the os to occur in cases of convulsions.

Dr. W. GOODELL said that in such cases he thought the best treatment would be to deliver per vaginam. Dilate and deliver by forceps or by turning; if the os were not readily dilatable, he would incise it.

Dr. ATKINSON mentioned a case in practice, where the patient from the sixth month had been afflicted with chorea. He was not informed of this condition until labor had commenced. The convulsive tendency was so strong that the patient was with difficulty kept on the bed. As he had before remarked in such cases, the dilatation was rapid, and the delivery was speedily accomplished. All the symptoms immediately disappeared, and her recovery was unattended with any untoward symptoms.

Dr. JAMES H. HUTCHINSON then read a paper on "The Use of the Ophthalmoscope in the Diagnosis of Cerebral Disease."

Dr. L. TURNBULL, being called upon, said that he was not prepared to enter upon an elaborate discussion of the subject, but would state that he was interested in the paper, and pleased with the clinical facts therein contained, as confirming the importance of the ophthalmoscope as an aid to diagnosis in general practice. It was in the year 1851 that Prof. Helmholtz published his "Description of an Eye-Mirror for Examining the Retina of the Living Eye," and in May, 1853, Dr. Turnbull first employed this valuable instrument. "I published," said Dr. T., "a series of communications in reference to its clinical use in diseases of the eye in the summer of 1859.* Neither Helmholtz nor any one at that time had any idea that it would be an aid to the general physician in the diagnosis of some of the most obscure affections of the brain, kidneys, etc. I advocated at that

* Medical and Surgical Reporter, Philadelphia, June 25, 1859.

time its general use, in the following language: 'Its employment requires about as much ingenuity and the same amount of time and attention as is necessary to become expert with the stethoscope' (Op. cit., p. 262). Its adoption, even by the ophthalmologists of that day, was opposed, as I stated in the same article, as follows: 'As is usually the case with every innovation upon old ideas, there is found a certain amount of opposition to its employment (even at the present day), and, as would naturally be anticipated, it comes from the same class of men who so strenuously opposed the introduction of auscultation, vaccination, anaesthesia, and other equally valuable adjuncts to our profession, and who are equally well represented outside of our profession by the opponents to the introduction of gas for illumination, the electric telegraph, steam in heating, etc., etc. Being unwilling to learn the use of the ophthalmoscope by the sacrifice of time and labor, they endeavor to produce its condemnation by a variety of objections.' In a reprint of these clinical observations* (1865), three years after my first use of the instrument, I brought to the attention of physicians its great value in Bright's disease of the kidneys, giving the ophthalmoscopic appearances; and here I would advise caution in the beginner with the instrument in this disease, else he will be apt to meet with disappointment, for all the illustrations of this disease are given in its advanced stage. At the outset, the appearances do not afford any special characteristics. At page 14 I bring forward the proofs from Bouchut† and Robin that 'the ophthalmoscope had been found useful in the diagnosis of granular meningitis' (*Gazette des Hôp.*, 1862). Twenty-three cases of meningitis had been examined by Bouchut, and the changes in the eye-ground were given and confirmed by Robin. And here I would utter another caution: that in all important cases it is well to have the ophthalmoscopic appearances confirmed by an expert with the instrument, as it requires constant, almost daily, use to keep the eye of the observer in training. So that no mistake should happen, abundance of time must be given to each case. I have seen a patient in whom much distress of mind was induced by a general surgeon mistaking a natural excess of pigment for a severe disease of the retina. In the examination of the retina of the negro, do not confound its bluish-gray normal color with a diseased condition." In concluding his remarks, the speaker desired to impress upon the hard-working physician not to neglect the use of the microscope and ophthalmoscope in deep-seated diseases of the eye, brain, and kidneys; in neglecting any of these aids to form a correct diagnosis he is culpable, and is not doing justice to the valuable lives placed in his hands. Cases of such neglect Dr. T. has met with even under the care of intelligent and capable physicians and surgeons. Those desiring to study the use of the ophthalmoscope in diseases of the nervous system he would refer with much satisfaction to the work of Allbutt,‡ which contains almost everything on this subject up to its date of publication (1871) worth knowing. The author has arranged his subjects well, describing first the anatomy of the optic nerve and retina so far as it is needful, then tracing the mode and time of variation from the healthy standard. Having done that, he describes the various diseases in turn in which optic changes are associated, as, for instance, encephalic, spinal, renal, and the mode of investigating the states of the optic nerve and retina.

* Defective and Impaired Vision, with the Clinical Use of the Ophthalmoscope in the Diagnosis and Treatment of Diseases of the Eye. 8vo, pp. 36. Philadelphia, Lindsay & Blakiston, 1865.

† See paper on "Medical Ophthalmoscopy" by M. Bouchut (*Medical Times and Gazette*, January 23, 1875), confirming his early observations; and he is about to publish a large atlas of medical ophthalmoscopy.

‡ On the Use of the Ophthalmoscope in Diseases of the Nervous System and of the Kidneys; also in certain other General Disorders. By Thomas C. Allbutt, M.A., M.D. Cantab. Pp. 405. London and New York, Macmillan & Co., 1871.

Dr. STETLER asked Dr. Turnbull whether the ophthalmoscope is of any use in deafness.

Dr. TURNBULL, in reply, said that as yet the ophthalmoscope has not been of much use in the diagnosis or treatment of deafness; the early cases in which it has been employed were of deaf-mutism, in which there was found retinitis pigmentosa. In cases of deafness and blindness after cerebro-spinal meningitis there is suppurative choroiditis, which may be diagnosed by the yellow or yellowish-white reflex we obtain from the pupil by means of the eye-mirror. This same condition of the eye is also found in cases of what is termed brain or cerebral deafness, following puerperal fever, meningitis, pyæmia, typhus and typhoid fever. Mr. James Hinton (*The Questions of Aural Surgery*, p. 284) states that Dr. Bader examined by the ophthalmoscope for several months together every patient with deafness who came to him with symptoms which he considered of a nervous character. With few exceptions he found hypermetropia present; and he considered it to be due not to flatness of the eyeball, but to "a certain form of paralysis of the third nerve;" no other affection of the eye was found to prevail. The subject is worthy of further study and investigation.

Dr. STETLER referred to a case of stercoraceous vomiting reported by Dr. Taylor at a previous meeting, and expressed a doubt whether fecal vomiting is possible as long as the ileo-cæcal valve is intact, this being a perfect valve and preventing regurgitation. Dr. S. was taught, and still believed, that the characteristic odor of the fæces is acquired in the colon, or that the function of the colon is fecocification. It is doubtful whether, in the so-called cases of stercoraceous vomiting, the matter is genuine fæces. Nature would revolt at such a spectacle.

Dr. J. TYSON said that if the term fæces be confined to the contents of the rectum, then much which is now spoken of as fecal matter must be excluded from that substance. But this he deemed erroneous; for the contents of the lower end of the small intestine are as much fecal matter as those of the large bowel, differing chiefly in consistence. The effete matters, including the odorous substances which are contributed to the residue of the food, are added in the small intestine as well as the large. Formerly it was thought that it was the special office of the solitary and agminated (Peyerian) glands to contribute these matters, but the more modern and, in his conception, the correct view assigned to these follicles the rôle of lymphatic glands,—that of blood-corpuscle factories,—so that the excretory function must be confined to the follicles of Lieberkühn. Moreover, he thought it not impossible for this valve to yield to pressure from below under abnormal conditions.

Dr. W. R. D. BLACKWOOD was satisfied that fluids would regurgitate or be forced through the ileo-cæcal valve. In a recent case of intussusception of the ileum in his practice, large quantities of fecal matter were vomited, differing in no manner from ordinary fecal dejections from the rectum, except in consistence. The intussusception was overcome by forcing a large quantity of warm salt water into the rectum, and the final injection must have passed the valve, because salt was evident to the taste in subsequent vomiting, which occurred in a few minutes after giving the injection.

His friend Dr. W. C. Phelps, who assisted him, was satisfied both that fecal vomiting took place and that the salt water passed the valve. He has seen water pass from the rectum into the ileum in the dead body, and there was no evidence of disease in the intestine at any point.

Dr. H. ALLEN said that the valve aids in preventing regurgitation, and yet he could conceive of conditions in which regurgitation might occur.

Dr. O. H. ALLIS said that he had witnessed many

cases of obstinate vomiting, but in no case was there any suspicious odor present. In a case of concealed strangulated hernia, that proved fatal on the sixth day, and in which vomiting was persistent, there was no odor of fecal matter.

REVIEWS AND BOOK NOTICES.

SERIES OF AMERICAN CLINICAL LECTURES. No. II. ACUTE RHEUMATISM IN INFANCY AND CHILDHOOD. By A. JACOBI, M.D. New York, G. P. Putnam's Sons. Pp. 62; price 40 cents.

The occurrence of rheumatism among children has been regarded by many as unfrequent; Dr. Jacobi, however, believes the affection to be quite common, but often overlooked. After a full discussion of the diagnosis and pathology of the disease, he devotes several pages to the various modes of treatment adapted to the various symptoms. Rest for the joints in a semi-flexed position, the application of ice in the acute stage, and hot poultices when the temperature has been reduced, in order to hasten absorption of the effusion, are some of the remedies to be first applied. Later, when it may be supposed that no further absorption of effusion will take place, gentle compression by collodion, flannel bandages, cotton with linen bandages, elastic bandages, plaster of Paris, will be found serviceable. Puncture of the joint and the use of the aspirator cannot be objected to when the contents are purulent, and may sometimes be used in copious serous effusion. The mild galvanic current also hastens absorption. The usual anodynes are to be used locally for the relief of pain. Internally, to relieve vascular pressure, aconite, digitalis, veratrum, colchicum, or quinia is administered. The latter Dr. Jacobi thinks of great value. The bisulphate or muriate may be given in a dose of five grains once, twice, or three times daily to a child of one or two years. Where the stomach rebels against the remedy, the rectum may take its place. The lecture concludes with a few remarks on the choreic manifestations of rheumatism, in which ergot in large doses is recommended.

GLEANINGS FROM OUR EXCHANGES.

EXTRACTION OF A CALCULUS FROM THE BLADDER THROUGH A VESICO-VAGINAL FISTULA.—A woman aged 66 was admitted to the West London Hospital, August 25, 1875, under care of Mr. Teevan, suffering from a vesical calculus.

On examination, a fistula admitting the tip of the finger could be felt in the roof of the vagina, and a stone apparently of small size was struck by the sound, lying close to the fistulous aperture.

On September 1, at 3 o'clock P.M., the patient having been put under the influence of ether, Mr. Teevan introduced a pair of narrow-bladed forceps into the bladder through the vesico-vaginal fistula, and, having grasped the stone, which was lying above the hole, extracted it by gentle traction. The calculus was phosphatic, ovoid in shape, and measured one and three-eighths inches long, and two and three-fourths inches in circumference. The knife was not used, but a few drops of blood escaped from the distended edges of the fistulous opening. The bladder was then examined with the finger, and found to contain a large quantity of mortar-like debris, which was removed with a small scoop. The viscus was then washed out, but no attempt was made to close the fistula, as the parts were in too unhealthy and inflamed a condition to admit of any

operation for that purpose. The patient's sufferings ceased after the removal of the stone, but she still complained of a "soreness," owing to the urine dribbling away; and, at her own request, she left the hospital on September 22.

Soon after her return home, she again began to pass pieces of "grit," accompanied with much pain. Not long afterwards the patient's feet and legs became dropsical, and she died on December 6, rather more than three months after the extraction of the stone.

Mr. Teevan ascribed the existence of the fistula to either the ulceration accompanying chronic cystitis, or to the result of the employment of a metal catheter, which had been used for some time by an unprofessional person.

CASE OF SPINAL PARALYSIS IN AN ADULT RESEMBLING THE SO-CALLED INFANTILE PARALYSIS.—Dr. D. F. Lincoln reports the following case in the *Boston Medical and Surgical Journal* for March 25: A tall, stout man, 49 years of age and of previous good health, noticed one morning, without any previous symptoms, a feeling in his legs as if they had fallen asleep. The feeling came on again and again through the day, and he began to be a little weak in the legs. In the afternoon, when trying to step upon the platform of a street-car, he failed, and had to be helped in. On arriving home, he was able (with assistance) to walk up-stairs to his bedroom, and went to bed, where he remained.

When seen by Dr. L., two days later, he felt well, no giddiness, muscles of face and eyeballs under perfect control, pupils normal in size and contracted well, speech natural, vision and hearing without defect. The bladder and rectum performed their functions normally. The senses of touch, pain, and temperature were normal in the hands, and nearly so in the feet. Reflex contractions could scarcely be obtained from the soles. There were no abnormal sensations. Pulse 80, temperature 98°. No albumen in the urine.

The muscles of the neck and limbs, except below the knees, were generally in a condition of semi-paralysis. He lay on his back, almost helpless; could not raise his head from the pillow without some help, and could not raise his knees from the bed by flexing the thighs. The grasp of his hand was very feeble indeed. There was no paralysis of any muscle. Below the knees he seemed to have more strength. The weakness was much more marked on the left than on the right.

Treatment consisted at first in nux vomica and cinchona, and subsequently tincture of iron with strychnia, and Horsford's acid phosphates of lime and magnesia. On the fifth day of the attack, treatment by the induced electric current was begun, when it was found that some, at least, of the muscles had lost part of their susceptibility to this stimulus. The loss went on increasing until the twenty-first day, when the galvanic current was substituted, a descending current being applied to the spine, and interrupted currents to the muscles, three times a week; the faradic current was also continued for a few weeks.

The hot-air bath to profuse perspiration was used just before the application of the currents, together with regulated gymnastic exercises. The paralysis of the muscles was gradually relieved under this treatment to a very considerable degree. The patient's improvement was very gradual, and it was six months before he was able to ride out. He finally was enabled to attend to his business pretty much as before the attack.

RARE CASE OF UNCONTROLLABLE VOMITING (*Boston Medical and Surgical Journal* for April 8; from *L'Union Médicale*, January 19).—A woman 50 years of age, suffering from caseous pneumonia of the right lung with cavities, presented the symptom of uncontrollable vomiting, which had persisted for five months. A sensation

of excessive pain and oppression was always present in the epigastrium as soon as she had eaten, while it was absent when she fasted. Upon the ingestion of food, especially that which was solid, the pains were such that the patient would roll in her bed and cry out until she was relieved by vomiting. This occurred every time that food was taken, and alimentation was limited to a few grammes of milk daily.

The autopsy showed the stomach to occupy nearly the whole of the sub-umbilical region. The organ was clearly divided into two parts, being twisted upon its centre. The upper part was very much distended, the lower part quite empty. The twist being unwound, the organ appeared like an hour-glass-shaped stomach with a central contraction. Removed and inflated, the stomach presented its natural form and showed no traces of the contraction. There was only a slight catarrh of the mucous membrane at the contracted point; all the rest of the organ was normal. The intestines, compressed to a very small volume, were scarcely visible.

CASE OF ACUTE OTITIS MEDIA; SUPPURATIVE INFLAMMATION OF THE MASTOID REGION; DEATH.—Dr. F. M. Pierce reports the following case in the *British Medical Journal* for March 6:

A youth of 16, who had never had any fall or blow upon the head, had noticed about four weeks previously slight deafness and pain in the right ear. About a fortnight later, the mastoid process became swollen and tender. A week previous to his examination, after severe pain in the ear and about the temple, a purulent discharge came from the right auditory meatus.

At the time when he was first seen he complained of severe pain in the depth of the ear, about the mastoid and down the neck. There was a profuse purulent discharge from the right ear; the mastoid region was greatly swollen, red, and soft, causing great projection of the auricle. No paralysis, nor any affection of the cranial nerves. A lotion of sulphate of zinc and carbolic acid was used, and an incision made into the mastoid swelling without liberating any pus. No vomiting, delirium, nor hemorrhage from the external meatus.

On the subsequent days severe pain in the back of the head, which had been relieved by the incision, returned, depriving the patient of sleep. There was no vomiting, delirium, nor hemorrhage from the meatus. In the course of the next few days the discharge from the mastoid region became profuse and offensive; that from the meatus diminished. The patient was restless, frequently tumbled down, and kept his head clasped between his hands, which he said relieved the pain at the back of his neck and head. Convulsive movements of the left arm and leg were now very noticeable. A day or two later all the symptoms had become more marked, when, quite suddenly, the left side of head and ear changed to a dark-purple hue, his head dropped forward, and he died. Unfortunately, no post-mortem examination could be obtained.

SOME PRACTICAL HINTS CONCERNING THE CARE OF NEW-BORN CHILDREN.—Dr. Buckingham (*Boston Medical and Surgical Journal*, March 25) says that under ordinary circumstances the first thing to be done for a child is to clean it. Get rid of the salve-like vernix caseosa by rubbing the body with oil and then washing with soap and water. He has sometimes used the oil alone, working it well in at all points, and then rubbing dry with a towel. Oil is as clean as soap. The object of washing is to get rid of dirt, and whatever will remove the particular kind of dirt in question, whether soap or oil, is the best thing for its removal. Alcohol is objectionable, as it dissolves the oily matter from the skin, and has a tendency to chill the child. Once being made clean, it is not necessary that the child should have an entire bath daily. The nates and neighboring

parts should be kept clean, even if they have to be washed with every change of napkin. A very important point is the necessity for drying the skin thoroughly before dressing. A good rubbing with the hand after the rubbing with the towel is agreeable to the child. Flesh-powder or powdered starch is not so good, and, besides, these applications frequently become acid and irritating.

The still adhering umbilical cord should be cut short, and covered sufficiently to protect the clothing. If it is not tied until the pulsations in it have ceased, there will be no risk of hemorrhage from its cut extremity. Dr. B. would never cut the cord till all pulsation in it was stopped. The cord should be short, the ligature small, the covering ample; and if the latter become offensive in a day or two it should be removed. The belly-band should not be too tight. Strings on it are better than pins, if either be used; but the best band requires neither, being broad, thick, loose, and elastic, woven or knit of good woollen yarn.

THE NASAL DOUCHE.—In a paper read before the New York Medical Library and Journal Association, Dr. Beverly Robinson alludes to the wide-spread idea which is supported by some of the best authorities as to the frequent danger of using this appliance. Physicians are loath to abandon it, however, Dr. R. thinks, "as it is thought to be so thorough in its work of cleansing the nostrils and pharynx."

The latter generally received opinion is, however, an error in Dr. Robinson's opinion, and he endeavors to demonstrate the truth of his assertion by an examination of the relations between the stream thrown by the douche and the anatomical structure of the nasal passages.

He shows that the stream must issue from the nasal orifice of exit before it has flooded the upper part of the nose, and when from some obstacle the flow is interrupted this flooding could only take place for a few moments, when the pressure in the naso-pharyngeal space would be such that the soft palate would give way almost immediately.

The effect of this would be that some of the liquid would pass into the stomach, or in the confusion of breathing get into the larynx. He does not believe that either the vault of the pharynx, the superior and middle turbinated bones, or the superior meatus are cleansed at all by the nasal douche.

TWO CASES OF TRANSFUSION.—Dr. D. Clarke reports the following cases in the *Canada Lancet* for April 1.

The first was that of a woman 33 years of age, the subject of advanced phthisis. The operation was commenced by the direct method with Aveling's apparatus, but, as this was found not to answer, defibrinated blood to the extent of six ounces, containing a small quantity of spirits of ammonia, was injected.

Although some alarming symptoms followed the operation, yet the patient survived, and two months later was still living, auscultation and percussion showing no change in the parts affected.

The second case was also a woman of middle age, who had been the subject of phthisis pulmonalis for about a year. Six ounces of blood were injected by the direct method by the aid of Aveling's improved two-bulb apparatus, a solution of salt being used in the vessel instead of ammonia. The patient survived the operation, but sufficient time had not elapsed at the date of reporting to enable any estimate to be made of the permanent result likely to be gained.

EXTRACTION OF FOREIGN BODIES FROM THE EYE.—A correspondent of the *Lancet* writes as follows:

"SIR,—In consequence of the difficulty I experienced in removing from a patient a portion of steel deeply imbedded in the cornea, which did not yield to spud or

needle, some other means for its removal became necessary. Dry, white soft silk waste suggested itself to me, and was wound round a thin piece of wood, so as completely to envelop its end. This soft application was then brushed once backwards and forwards horizontally over the part of the cornea where the foreign body remained fixed. To my astonishment, it was at once entangled by the delicate but strong meshes of the silk, and was withdrawn with the greatest ease, caught by the same. Seeing no books (which I have consulted) mention this application, and feeling sure it is one of great value in removing foreign bodies fixed or floating in the conjunctiva or cornea, it seems to me a simple but valuable invention."

POISONING BY CHLORAL HYDRATE: RECOVERY.—Dr. Snell (*British Medical Journal*, March 27) was called to see a druggist's assistant who had swallowed a solution containing probably not far from an ounce of chloral. The patient was found breathing heavily, at times stertorously; face dusky, pupils contracted; pulse weak and about 76. He could not be roused, and made no attempt to answer the questions put to him. It was ascertained that he had not swallowed the chloral more than twenty minutes previously. An emetic was immediately administered, and the patient vomited freely. Gradually the breathing improved, consciousness returned, and after a few hours' rest he appeared perfectly well.

MISCELLANY.

WHITE COAL.—A new kind of fuel has been discovered on the Australian continent, which has received the name of white coal. It consists of felted vegetable fibres, like peat, which contain, interspersed between them, fine grains of sand. It is easily combustible, and burns with a light flame. The white coal covers large tracts, requiring no mining, and is already used in large quantities as fuel.—*Scientific American*.

CHARACTERISTICALLY SPANISH.—In a lecture on the relative procreateness of the sexes, Dr. Schlemmer (*Allg. Wiener Med. Zeitung*) mentions the fact that Isabella of Aragon, about the latter part of the fifteenth century, issued a decree fixing (not limiting) the number of conjugal embraces per day at six.

NOTES AND QUERIES.

PHILADELPHIA, April 30, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—At the request of Dr. W. S. Forbes, I send you the subjoined letter for publication, in order to correct the misstatement alluded to.

Very truly yours,

W. W. KEEN, M.D.

PHILADELPHIA, April 12, 1875.

DOCTOR W. W. KEEN.

MY DEAR DOCTOR,—I have just read with pleasure your published lecture, "A History of the Philadelphia School of Anatomy and its Relations to Medical Teaching." It is written with vivacity, and no doubt will be read hereafter with interest. There is a statement in it, however, concerning myself, made inadvertently, no doubt, which has no foundation in fact, and which I take leave to correct. You say that "in 1856, while Doctor Agnew was teaching, Doctor Forbes opened his school, which was designed largely to give facilities for dissection to the students of the dental colleges, in one of which he was Professor of Anatomy." Now the fact is this: In 1858-59 I had in my anatomical class one hundred and ninety-

two students of medicine, and in the spring of 1863, just five years afterwards, I was elected Professor of Anatomy in the Pennsylvania College of Dental Surgery, the only college of dental surgery then open in Philadelphia. The matriculants of this College in 1863 were only forty-four in number. In addition to lecturing in my own Anatomical School, I lectured in the Pennsylvania College.

In regard to my teaching, it may be added that, in the twelve years during which my school was open I taught eighteen hundred and sixty-seven students anatomy and operative surgery.

In March, 1867, just after the winter lectures, the Legislature of the State, after much exertion on the part of the committee appointed by the College of Physicians, of which I was chairman, passed my "Anatomical Act," a very notable event in the history of medicine in this country. This "Act" forbids, under penalty, the sale of dead human bodies for any purpose whatsoever. It legalizes dissection, and makes it free.

Yours very truly,
WM. S. FORBES, M.D.

No. 1405 LOCUST STREET.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

At a meeting held April 28, 1875, the following resolutions, presented by Dr. G. Hamilton, were adopted:

Resolved, That the members of the Philadelphia County Medical Society have learned with regret the death, March 31, 1875, of Dr. D. Francis Condie, one of the founders, and at one time president, of this Society.

Resolved, That in the decease of Dr. Condie the Society recognizes the loss of a former member who was long distinguished among his fellows by the constancy and zeal manifested at all times and upon all occasions in the support of whatever tended to fulfil the objects for which the Society was instituted, and in the exaltation and maintenance of its character and reputation.

Resolved, That by the death of Dr. Condie the profession has lost an indefatigable student, and an author whose stores of practical knowledge, strong common sense, and large experience had enabled him to contribute much valuable matter for the guidance of the practitioner.

Resolved, That in integrity and general moral worth the life of Dr. Condie merits our fullest approbation, and that in his spirit of benevolence, prompting him in early life to aid as a pioneer in the foundation of the first temperance society of Pennsylvania, the community has cause to hold his memory in grateful remembrance.

Resolved, That, while deploring the loss of our late member, we have nevertheless reason for thankfulness in the length of days granted to him, and that, in the wisdom of a Providence that cannot err, soundness and strength of intellect were vouchsafed unto him until near the close of his existence.

NORTHERN MEDICAL ASSOCIATION OF PHILADELPHIA.

A STATED meeting of the Northern Medical Association of Philadelphia will be held at their hall, 608 Fairmount Avenue, on Friday evening, May 14, at 8 o'clock.

Subject for discussion: Diphtheria. To be introduced by Dr. S. H. Griffith.

The medical profession are cordially invited.

ERRATUM.

THE author of the article on typhoid fever in our issue of April 24 was Dr. George, not J. G., Hamilton.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM APRIL 27, 1875, TO MAY 3, 1875, INCLUSIVE.

HEAD, J. F., SURGEON.—Announced as Medical Director of the Department. G. O. 3, Department of the South, April 30, 1875.

BACHE, D., SURGEON.—Relieved from temporary duty at Baltimore, and to resume his duties at Fort McHenry, Md. S. O. 76, A. G. O., April 28, 1875.

WEEDS, JAMES F., SURGEON.—Transferred from Department of Dakota to Department of the South. S. O. 75, A. G. O., April 27, 1875.

WOLVERTON, W. D., ASSISTANT-SURGEON.—Transferred from Department of the South to Department of Dakota. S. O. 75, c. s., A. G. O.

SEMIG, B. G., ASSISTANT-SURGEON.—Assigned to duty at Fort Yuma, California. S. O. 25, Department of Arizona, April 12, 1875.

SATURDAY, MAY 15, 1875.

ORIGINAL LECTURES.

CLINICAL LECTURE ON VENEREAL DISEASES.

BY F. R. STURGIS, M.D.,

Lecturer on Venereal Diseases in the Medical Department of the University of New York, etc., etc.

Delivered at the Charity Hospital, Blackwell's Island, New York, April 12, 1875.

NO. I.

GENTLEMEN,—I have two interesting cases to show you to-day. The first is a case of the primary lesion of syphilis in a woman, extremely well marked. The history of the case is briefly this. She cannot give the exact date of the appearance of the lesion, but she says it has lasted for seven weeks. The ulceration is extremely superficial, looking as though the epithelium merely was stripped off. It differs entirely in appearance from what we find in the *chancroid*. The edges are flush, and level with the surrounding surfaces; in the chancroid they are usually undermined. With the chancroid there is a large amount of secretion; with this, you see, it is slight.

There has been but little treatment in the case, the patient having been in the hospital about two weeks. You will notice that the so-called induration which surrounds the sore is extremely well marked. This induration is not a necessary accompaniment of the primary lesion, although when present it is of value. There are three different varieties which we recognize: 1, the Hunterian indurated chancre; 2, the parchment indurated chancre; and, 3, the erosiform indurated chancre. This latter variety has hardly any induration at all.

Another characteristic of this sore is its superficial character. There is no ulceration, in the true sense of the word. With the chancroid, you know that there is an actual loss of tissue; here there is little, if any. The period at which these ulcerations should make their appearance is from three to four weeks after the infecting coitus. In the large majority of cases it will be impossible to arrive at an exact date, especially in women: usually, it commences from the twenty-fourth to the twenty-sixth day after connection; sometimes later; occasionally, but very rarely, earlier. Those rare cases you will occasionally see, and it then sometimes becomes a nice point in the diagnosis to determine whether a given sore is chancroidal or syphilitic.

These primary lesions progress very slowly. In this case, our patient noticed a little papule which extended slowly, but, as it was during her menstrual period, nothing could be done for it. The ulceration has been larger than it is now. The primary lesion of syphilis has a tendency to get well if allowed to, oftentimes healing up in a few days; whereas the chancroid is inclined to spread.

With regard to the treatment of the primary lesion, the simpler it is, the better: merely local

dressing, separation of contiguous surfaces, and perhaps dusting over with a powder, will suffice; only in rare cases will cauterization be requisite. You are much more likely to irritate and keep up your sore from the use of the cautery, than if you let it alone. With regard to commencing treatment at once, there are various opinions,—some in favor, some against. I think it better to wait, for two reasons. In the first place, you are often unable to decide upon the character of the ulcer; and, knowing that mercury is absolutely injurious to chancroid, it is well to abstain until this point is settled by the appearance of the secondary symptoms. In the second place, giving the mercury *ab initio* will not prevent the appearance of subsequent lesions, but it does have the disadvantage of retarding them, sometimes for several weeks. You are then entirely abroad as to the nature of your disease, and in doubt whether to continue treatment or not. Another point: you do no harm to your patient by waiting, as the virus does not accumulate by delay, and therefore I say to you that the most simple treatment will very often be the best.

These lesions of syphilis are usually single, seldom multiple; while with the chancroid the opposite obtains. These lesions, moreover, are not auto-inoculable, the disease, as a rule, giving immunity from a second attack to the person the possessor of it. In making the attempt at auto-inoculation, you may get a small pustule, but this disappears in forty-eight hours. You do not get a new primary lesion; whereas in the chancroid you can perform auto-inoculation from the time of its appearance until the time of its cicatrization.

The next case I have to show you is one of chancroidal phagedæna, where the ulceration has run almost around the entire glans penis.

One word with regard to this phagedæna. It is not a constituent of either the chancroid or the primary lesion, but is a complication, and a serious one, denoting, as it does, a vitiated condition of the general health, either from some inherited taint, alcoholism, or other debilitating cause. You will sometimes find that as fast as it heals at one edge it extends in another; you then have what is known as a serpiginous chancroid.

This patient had gonorrhœa one year ago, and subsequently had a sore on his penis, which disappeared after treatment in a short time. The present sore appeared ten days after connection, and spread rapidly. Here you notice the short time which has elapsed between the appearance of the sore and the time of connection, differing in that respect from what takes place in the indurated chancre. In the next place, you see that there is quite an extensive ulceration along the base of the glans penis and beneath the sheath of the organ. The amount of secretion is also very abundant, and the edges of the sore, as you see, are ragged and undermined; indeed, at one point the ulcer has burrowed for quite a distance. In other words, a decidedly destructive process has been going on. Besides this, the entire organ is doughy and œdematous. On handling the base of the ulcer we are struck at once

by the fact that it is perfectly soft, and devoid of the hard cartilaginous ring of induration which surrounds the primary lesion; and on inspecting the groin we find no indurated or swollen glands. These are points of much diagnostic importance, for the presence or absence of induration in the inguinal glands, as well as in the ulcer, marks the difference between the chancroid and the chancre, the simple non-constitutional venereal ulcer and the specific constitutional one.

This phagedæna is a complication of much consequence. It may attack both the primary lesion (chancre) and the chancroid, but is not a component of either, nor does it belong to one more than to the other. If it attack the syphilitic ulcer, it will carry off the induration; but still this does not change the character of the sore; subsequent symptoms will make their appearance, and usually in such cases they are likely to take on ulcerative action. In this case, the progress has been rapid; the ulcer has extended in less than a week, and burrowed beneath the skin of the penis and down the glans penis itself. The ulceration has that peculiar appearance which is found in these chancroids. It has an abundant secretion and undermined edges; and these edges are important in the treatment by cautery, for you must remember to cauterize not only the surface of the sore itself, but beneath the edges; otherwise, you may have to cauterize two or three times over, if you neglect this slight precaution. What is true in the treatment of the ordinary chancroid is doubly true here: destroy the ulcer thoroughly and quickly. But how are we going to get at it in order to cauterize it? Sometimes we are able to retract the prepuce; but in this case it is impossible to get it back, and then the next best thing to do is to inject a medicated solution beneath the prepuce, in order to cleanse and alter the character of the sore. Should this be impracticable, we might dilate the prepuce with pieces of sponge packed between it and the glans, just as we would an os uteri; and, if all these methods fail, then we may lay the ulcer open by a free incision. It is important to expose the sore thoroughly in order to cauterize it properly; and it is better to cauterize into sound tissue than to do it imperfectly. If you are compelled to resort to an incision, do not forget to cauterize the cut edges of the wound as well, otherwise they will become inoculated.

Before leaving the subject of chancroid, gentlemen, let us devote a few minutes to a consideration of their seat. It was for a long time believed that the head and face possessed an immunity against chancroid, and that any venereal ulcer seated upon these parts must be syphilitic. It is true that in a large proportion of cases such is the fact; but later research has shown that the chancroid may, and does, appear upon the lips, face, and other parts of the body.

There is an interesting case of this kind in the wards, where the ulcer, primarily seated upon the genitals, was inoculated upon the face, behind the ears, upon the body, hands, and wrists, by the patient himself, notwithstanding that he had been warned of the danger of auto-inoculation.

The primary lesion, unless complicated, as a rule, gets well rapidly. The chancroid, on the other hand, has a tendency to extend almost indefinitely, especially if it become phagedænic. In these ulcerations we have a period of incubation of only a few days at the most. In the primary lesion we have a period of incubation of several weeks. It may not always be easy to get exact dates, from the patient's uncertainty about it, but in the majority of cases you will find that the period of incubation in the syphilitic ulcer is from three to four weeks. The glandular induration, with the primary lesion, is rarely absent. Sometimes it is slight, sometimes well marked; whereas in the chancroid, generally, you have no complication of the inguinal glands whatever. When there is, the resulting bubo nearly always assumes the character of the sore itself,—i.e., is chancroid; oftentimes undermining the tissues to an alarming extent.

Another point is the multiplicity of these lesions. Chancroids are often multiple; the primary lesion very rarely. The former is auto-inoculable, the other is not. Even if at the time of infection the chancroid be single, it nearly always becomes by-and-by a multiple sore,—that is to say, any abrasion of the skin is likely to become chancroid; whereas, with the primary lesion, the infection once given, the system is no longer susceptible to a fresh inoculation. German investigators have made the attempt to inoculate the bearer of the primary lesion with the secretion of the sore, with but little effect. All that has been done is this: the skin of such patients is usually irritable, and the secretion may produce a small pustule; but this pustule comes on very soon after the inoculation has been made, and disappears in a short time; showing, by the absence of all the diagnostic signs of the chancre, that it is a false lesion, so to speak. In the primary lesion the ulceration is superficial; it rarely goes deep unless it be complicated with something in the shape of phagedæna or gangrene. The presence of the induration is a valuable sign, but that may sometimes be absent; so that you have only the history of the case to guide you in forming your diagnosis. After it has lasted for some while, the chancre will sometimes assume a peculiar appearance; the floor of the ulcer becomes covered with an abundant crop of granulations, which spring up above the level of the surrounding tissues. Over these granulations will be spread, oftentimes, a thin film, looking not unlike mother-of-pearl, particularly when seated upon moist surfaces. If the primary lesion be seated upon parts exposed to the air, then you will sometimes find it covered over with a light crust. In other words, the chancre becomes converted into a mucous patch.

As a rule, an indurated chancre, after it has healed up, remains healed; but there are exceptions to this rule. It sometimes happens, especially if the induration has been extremely well marked and the cicatrization has been slow, that the chancre breaks out again without a fresh connection having been indulged in. Remember this, as otherwise you may think your patient is trying to deceive you.

ORIGINAL COMMUNICATIONS.

CLINICAL CONTRIBUTION TO THE SYMPTOMATOLOGY AND PATHOLOGY OF INTRACRANIAL TUMORS.

BY CHARLES S. BULL, M.D.,

Ophthalmic Surgeon to Charity Hospital; Assistant-Surgeon to the New York Eye Infirmary; Microscopist to the Manhattan Eye and Ear Hospital.

IN the *Times* for January 9, 1875, the writer reported a case of intracranial tumor with microscopic examination, which was somewhat rare as regards locality and symptomatology. The following cases are presented in detail for the sake of comparison with each other, and as a contribution to the symptomatology, prognosis, and pathology of the subject. It may now be said, with a certain amount of justice, that the physician should never be surprised at any variety of symptoms occurring in the course of a supposed case of intracranial growth. But there are a certain train of symptoms which we always expect to encounter in these cases. The histories of the following cases will show that the expected symptoms are sometimes wanting, and their place taken by others which obscure both diagnosis and prognosis, and leave us very much in the dark:

Case I.—A. C., æt. 50, Ireland, blacksmith. The patient has been an inmate of Charity Hospital several times during the past two years, suffering from asthma, chronic bronchitis, and emphysema. He was admitted for the last time on December 4, 1874, for a troublesome cough, with considerable expectoration and great dyspnoea. On physical examination, there were found the usual signs of chronic bronchitis and emphysema, and, in addition, hypertrophy of the heart. The man's face was constantly congested, and the extremities were cold, and almost livid. When he walked, his gait was tottering or waddling, resembling somewhat that seen in patients suffering from pseudo-hypertrophic muscular paralysis. There was no paralysis, however, of any muscle, and the cutaneous sensibility was perfectly normal. There was a moderate amount of deafness in the right ear, hearing-distance for the watch being $\frac{5}{4}$, but the man had chronic naso-pharyngeal catarrh, and a somewhat sunken membrana tympani, which would account for the deafness. There was no disturbance of vision, no strabismus or paresis of any of the ocular muscles, and the pupils were normal and reacted well. He remained in about the same condition till the last week in December, when he complained of pain and weakness in the lumbar region, became unable to sit up, lost his appetite, and his bowels became obstinately constipated. He next developed some obscure head-symptoms, fell into a drowsy condition, varied with low muttering delirium, from which, however, he could be aroused. He sank gradually away, and died on January 2, 1875, having been deeply cyanosed on the last day of his life. At no time were there symptoms of disease of the eye, though repeated examinations were carefully made with the ophthalmoscope. The day before his death, the pupils became widely dilated. A diagnosis had been made of a low type of meningitis.

Autopsy, thirty-three hours after death.—Bones of the skull normal. The vessels of the dura mater were filled with blood, and there were several points of adhesion between the dura mater and pia mater, on the right side, in the middle and posterior fossæ of the base.

The vessels of the pia mater at the base were engorged with dark blood. The subarachnoid space was very largely distended with fluid, as were also the meshes of the pia mater. The cerebral convolutions were flattened over the vertex, most markedly in the left middle lobe. The lateral ventricles were largely dilated, and filled with clear fluid. There were two or three circumscribed spots of meningitis at the base of the brain on the right side, in the middle fossa, near the median line, but there was very little solid exudation.

On the anterior and inferior surface of the right lobe of the cerebellum, underneath the pia mater, with attachment only to the vessels, was an oval, flattened, slightly nodulated and firm tumor, measuring two inches long, one-half inch broad, and one-half inch thick.

The growth projected into the internal auditory canal, pressed upon the right hemisphere of the cerebellum, the right side of the pons, right crus cerebri, and all the cranial nerves of the right side except the first, second, and ninth pair.

The lungs were emphysematous in the upper lobes, bronchitis all over both lungs, and general pleuritic adhesions. There was hypertrophy of the entire heart, dilatation of the right ventricle, but no valvular disease.

Remarks.—The above narrative is of a case of supposed meningitis, in which a cerebral tumor was unexpectedly stumbled upon at the autopsy, and which had manifested its presence during life by but a single symptom,—the staggering gait,—and this was not so marked as, in the absence of other symptoms, to be regarded as of special importance, and it was masked later in the disease by the symptoms of meningeal inflammation. Another interesting feature in the case was the encroachment of the tumor upon the internal auditory canal and its pressure upon the auditory nerve, which, of course, would account for the deafness. It seems singular that the pressure upon the third, fourth, and sixth nerves should have produced no phenomena in the muscles of the eye, which were carefully examined on several occasions, and found intact. Even the pupil was not affected until just before death. A microscopical examination of the optic nerve and retina revealed nothing abnormal.

The tumor proved, on examination, to be a sarcoma of mixed character, both small round cells and fusiform cells being found, though the former predominated. There was very little connective tissue in the growth, and very few blood-vessels. The tumor was circumscribed, and was entirely devoid of processes, with the exception of the one encroaching upon the internal auditory canal.

Cerebellar tumors are said to manifest themselves almost always by some affection of the optic nerve, either a neuritis descendens or "choked disk;" yet in this, both were absent.

Case II.—D. D., æt. 31, Ireland, coachman, admitted to Charity Hospital December 2, 1874.

The patient's mental condition was so much affected that no clear history could be obtained. The only fact of importance elicited was that about three weeks previous to his admission to the hospital his sight began to fail, and grew steadily and rapidly worse. The patient is a strong, finely-developed man, with dark complexion. His mind wandered at times, and it was difficult for him to concentrate his thoughts sufficiently to answer questions. His general health,

until recently, was perfect, but for about a month he had suffered from constant thirst and hunger, and marked diuresis. Vision was reduced to perception of light, and the pupils were moderately dilated and immovable. He drank an enormous quantity of fluid without quenching his thirst, and passed about three gallons of colorless, perfectly clear urine, which deposited no sediment. Its reaction was acid, specific gravity 1002-3, but it contained neither albumen nor sugar, though repeatedly examined. In the course of two or three days complete amaurosis set in, and he developed a slight muttering delirium at night, and later this came on in the daytime. Both eyes presented a typical case of "choked disk." The optic papillæ and retinæ were enormously oedematous and infiltrated with exudation from the vessels, which in many places were entirely concealed from view. The fundus of each eye was strewn with hemorrhages of varying size, some superficial, others deep in the tissue of the retina and papilla. The media were perfectly clear, the pupils immovable, and there was a slight tendency to ptosis. When spoken to, he always said he felt well, but complained of great thirst. He soon began slowly to emaciate, and incontinence of urine came on.

During the day he now developed an unsteadiness or staggering in his gait, and was also attacked with epileptiform seizures confined to one side, and at times affecting only the arm or the leg. These were infrequent and occurred at irregular intervals, rarely lasting more than a minute or two, and after them he fell into a semicomatose state.

On the 18th of December he began to show some slight signs of improvement; his intellect became clearer, and he spoke more rationally. A diagnosis was made of intracranial tumor, probably at the base of the brain, and involving both optic tracts and perhaps the cerebellum; but it was difficult to account for the great diuresis, unless perhaps the fourth ventricle was involved in the disease. His improved state lasted till the last of December, when he grew worse again; but there was no further return of the convulsive movements of the limbs. On January 16, 1875, a divergent squint of the left eye made its appearance, due to paresis of the internal rectus muscle. His pulse and temperature were taken twice daily, but his temperature never went above 100°, and averaged 98°; and though his pulse occasionally reached 115, yet it soon fell, and did not average above 92.

The process in the eyes went on rapidly to atrophy of the optic nerves, the exudation disappeared, the hemorrhages were absorbed and did not recur, and on the 10th of February the optic papillæ presented the picture of advanced atrophy, their edges sharply defined, the arteries reduced to threads, and the color a brilliant white.

The patient's condition again improved; the emaciation ceased, his appetite became less voracious, and, although he complained of the same devouring thirst, yet the amount of urine voided was somewhat less in quantity. His intellect became clearer; he left his bed and got up, and declared he felt perfectly well but for his blindness.

The treatment in the above case was mainly tonic and restorative, with potass. iodid. in large doses three times a day. On the supposition that the administration of this drug might be influencing the diuresis, it was discontinued; but there was no diminution in the amount of urine voided, and it was therefore again administered.

Are we to suppose that the potash had exerted its absorptive powers on the growth, and caused its gradual diminution or disappearance? or was the

diagnosis faulty? Authorities would have us believe that "choked disk" is always caused by an intracranial growth, and in accordance with this dictum the case must be ranked in this class. But, resting our knowledge on the results of pathological investigation, can we assert that patients may recover from intracranial growths?

Such a case as the one just cited is of great interest so long as the man lives, but just so long does it remain an enigma, the solution of which we can only attain by an autopsy.

Case III.—T. R., æt. 6, a well-developed, bright boy, was admitted to the N. Y. Eye Infirmary, October 12, 1874. About three months before, the boy had received a severe blow on the right temple from a bat, which made a ragged wound about two inches long. He was felled to the ground, lost a great deal of blood, and remained unconscious for nearly forty-eight hours. He recovered, however, and nothing wrong was noticed in his intellect or vision. One week later he fell from a wagon, and struck on the same temple; the old wound was reopened, and again a profuse hemorrhage was the result. When he recovered consciousness, he complained of violent headache, nausea, and vertigo, which lasted almost constantly for four weeks. Since then the nausea and vertigo have disappeared, and the headache has been very slight and inconstant. One week before I saw him the mother noticed that he could not see well, and that he fell over the furniture in the room, and could not find the door.

An examination showed moderately dilated pupils, which reacted well to light, freely movable eyeballs, and no squint. An ophthalmoscopic examination showed an extremely well-marked example of "choked disk" in both eyes. The outlines of the papillæ were entirely lost, the veins immensely engorged and distorted, a mass of exudation on both disks and into the retina immediately around them, and in the region of the macula a peculiar yellowish-white, glistening exudation, arranged in the radiate or stellate form so characteristic of retinitis albuminurica. On questioning the mother, she said the child had of late passed a good deal of dark-colored urine. A specimen was examined at once, but no albumen or casts found. The urine was examined at every visit, but nothing abnormal was ever found. Vision was reduced to perception of light.

October 14.—The child appeared heavy and stupid. Some minute extravasations of blood on the right optic disk. From the history, a diagnosis was made of basilar meningitis, although the presence of "choked disk" would seem to indicate an intracranial tumor. There is no interference in the function of any of the other cranial nerves, and not a sign of any disturbance in the cerebellar functions.

October 16.—The child has lost the dull, stupid look, and seems bright and intelligent, though somewhat quiet. The right optic disk shows signs of atrophy, the exudation is being absorbed, and the arteries seem smaller in size. From this time on the atrophic process went on rapidly; the hemorrhages became absorbed, the exudation into the retina and optic nerve disappeared, the papillæ regained their clearly-defined outlines, and the arteries became almost thread-like in size. The exudation in the region of the yellow spot, however, remained unchanged, and is probably of the same nature as that met with in retinitis albuminurica, viz., a fatty degeneration of the retinal tissue.

The treatment was carefully followed out, but proved of no avail. It consisted in repeated blisters behind the ears and to the nape of the neck, leeches to both temples, potass. iodid., six-grain doses three times a day, gradually increased to gr. xv three times a day,

and atropine instilled daily. After the inflammatory process had subsided in the nerves, resort was had to strychnia, with the faint hope of staying the atrophic process, and one-sixtieth grain was injected hypodermically every day, and gradually increased up to one-thirty-sixth grain, without producing any favorable result, and here we were obliged to discontinue it, as it began to produce the toxic effects. The boy was seen at irregular intervals up to January 15, 1875, and at the last visit the atrophy was complete, the amaurosis was total, and the pupils were widely dilated. The boy's health was perfect, and he was growing rapidly.

Remarks.—This case showed some interesting points. If the pathological process within the skull were a meningitis, it seems very strange that it did not produce any constitutional disturbance. Except during the two days of unconsciousness immediately following the accident, the child was not sick, and complained only of headache and occasional vertigo. Yet there was an active process of some sort going on within the skull when he was brought to the Infirmary, as was proved by the ophthalmoscope.

It could scarcely have been a tumor within the brain, for the lesion followed the accident too closely. Hemorrhage following the accident might have given rise to the signs of intracranial pressure indicated by the "choked disks," but it would also have caused other morbid phenomena of a paralytic nature, none of which were present.

In view of all the facts, it seems possible that there might have been a slight fracture at the base, perhaps produced by contre-coup, which had set up a localized meningitis, and the exudation, whether serous or otherwise, had pressed upon the chiasm or optic tracts, or perhaps upon both ophthalmic veins, though the former supposition is the more probable. From whatever aspect considered, the diagnosis is one of some difficulty, particularly in view of the recovery of the patient.

NEW YORK, March 20, 1875.

A CASE OF ACUTE PHTHISIS.

REPORTED BY GEORGE S. GERHARD, M.D.

THE following notes of a case in the service of Dr. James H. Hutchinson I publish by his permission.

Thomas McG., æt. 21, a native of Boston, and a book-cannasser by occupation, was admitted on February 19, 1875.

He stated that he was taken on the 9th inst., after an exposure while on a debauch, with a feeling of malaise, followed on the evening of the same day by a chill and fever, and on the following day by cough and mucous expectoration, but not by pain in the chest.

His previous health had always been good, and no history could be obtained of his ever having before suffered from any form of chest-disease. He also presented a good family history. His habits had been for some time intemperate, but he had never suffered from venereal disease.

When he was admitted, he had fever, a furred but moist tongue, and cough, accompanied by mucous expectoration. He did not complain of pain in the chest, and there was no marked dyspnoea and no blueness of the lips. There was a good deal of muscular trembling and general prostration, but the patient's mind was perfectly clear. Examination of the chest revealed slight

dulness anteriorly in the left infra-clavicular region, with increased vocal fremitus, and, posteriorly, impairment of resonance over the whole right lung, but the vocal fremitus was somewhat more marked on the left side. Auscultation revealed fine and coarse friction-sounds, and a good many subcrepitant râles both anteriorly and posteriorly, but the latter were especially numerous in the left infra-clavicular region. The heart-sounds were normal. The urine was free from albumen.

He was ordered quiniæ sulph., gr. j; pulv. ipecac. comp., gr. iij; potass. nit., gr. v; pulv. digital., gr. ½; q. t. h.

On the 20th the muscular trembling had increased, and two ounces of whisky daily were ordered. A.M., temperature 102°, respiration 30, pulse 96. P.M., temperature 104°, respiration 30, pulse 106.

On the 21st, dulness in the left infra-clavicular space persists, and there is blowing respiration in this region, but the other chest-signs remain unchanged. The patient's cough is growing more troublesome, but his expectoration is still bronchitic in character; there is some substernal soreness, but there is no localized pain in the chest, and no pain on full inspiration. Whisky increased to fʒvj. A.M., temperature 100°, respiration 30, pulse 94. P.M., temperature 103½°, respiration 30, pulse 94.

On the 22d, A.M., temperature 100°, respiration 36, pulse 86; P.M., temperature 103°, respiration 36, pulse 96.

On the 23d, A.M., temperature 99½°, respiration 36, pulse 96; P.M., temperature 103°, respiration 36, pulse 100.

On the 24th, A.M., temperature 101°, respiration 36, pulse 100; P.M., temperature 101°; respiration 36, pulse 100.

On the 25th the percussion-note at the left apex is dull and somewhat tympanitic in quality, and the râles are coarse and more numerous; posteriorly, there is no marked dulness on either side, but the râles (friction and subcrepitant) are still heard. The patient is very pale and weak, but he takes his nourishment well, and is not delirious. A.M., temperature 99°, respiration 36, pulse 86; P.M., temperature 101°, respiration 36, pulse 96.

On the 26th, cough very troublesome, and the expectoration is now viscid and streaked with blood; dyspnoea increasing, and the lips and nails are bluish, but there is no marked hectic disturbance. The whole left chest is dull on percussion posteriorly, and the subcrepitant râles are very numerous.

The chest was ordered to be dry-cupped. A.M., temperature 101°, respiration 42, pulse 104; P.M., temperature 102°, respiration 36, pulse 96.

On the 27th, slight delirium last night, but mind clear this morning. Dulness over left chest, posteriorly, unchanged; respiration distinctly bronchial in the infra-clavicular region and elsewhere; on the left side it is very harsh, and accompanied by friction and coarse crackling; there are also a good many râles on the right side. Lips decidedly cyanotic; tongue furred, but moist; no nausea or vomiting; bowels confined. Stimulus increased to fʒx. Powders stopped, and mixture ammon. carb. and infus. digital., fʒij every alternate two hours ordered. A.M., temperature 102°, respiration 36, pulse 96; P.M., temperature 102°, respiration 48, pulse 114.

On the 28th, percussion anteriorly on left side is of higher pitch and more tympanitic in quality; indeed, below the clavicle there is amphoric resonance and cracked-pot sound. Posteriorly, there is dulness on both sides, but it is especially marked on the left. A.M., temperature 101°, respiration 48, pulse 96; P.M., temperature 102½°, respiration 40, pulse 106.

On March 1, A.M., temperature 101° , respiration 42, pulse 100; P.M., temperature 103° , respiration 42, pulse 104.

On the 2d, A.M., temperature 101° , respiration 42, pulse 94; P.M., temperature 102° , respiration 42, pulse 100.

On the 3d, dyspnoea still more marked, and lips and nails very cyanotic; patient talks a great deal during sleep; pulse very feeble, and somewhat dicrotic; occasional sweating; cough and expectoration unchanged. Dulness greater on the right side posteriorly to-day; other signs as before.

On the 4th, increasing prostration; tongue brown and dry. A.M., temperature 100° , respiration 42, pulse 100; P.M., temperature 102° , respiration 36, pulse 94.

On the 5th, patient very delirious last night, and this morning there is marked mental hebetude and intense prostration. Amphoric resonance on left side anteriorly exceedingly well pronounced to-day.

On the 7th, moribund.

On the 8th, patient died at 2 o'clock this morning.

At the autopsy, which was made fourteen hours after death, the following note was taken. Body much emaciated; rigor mortis well pronounced. The left pleural cavity contains a considerable quantity of serous effusion, and at the base of the lung there are a few adhesions. There is also some effusion in the right pleural cavity, but it is smaller in amount, and of a darker color. There is no enlargement of the mediastinal glands. The left lung is solidified from apex to base by diffused caseous infiltration, and here and there cavities are found, but none of them are larger than a marrowfat pea. Scattered throughout the lower half of the lung there are numerous gray granulations (miliary tubercles). The same granulations are found in the right lung, but they are more uniformly disseminated, and are associated with comparatively few cheesy deposits. The tissue of the right lung is everywhere congested and of a dark color, but it is generally crepitant. There are no excavations in this lung. Heart and abdominal organs healthy. Careful examination of the brain and its meninges fails to reveal the presence of tubercles.

Remarks.—When the patient whose history is given above was admitted into the hospital, the physical signs presented were those of diffused bronchitis, with extensive plastic pleurisy. There was no decided dulness on percussion in any part of the chest, excepting at the apex of the left lung, and the general symptoms could all be accounted for by the physical signs. The persistence, however, of the physical signs, and the increasing dyspnoea and constitutional depression, soon led Dr. Hutchinson to conclude that he had a case of acute phthisis to deal with. The development of tuberculosis was undoubtedly of secondary occurrence, and was probably coincident with the increase of dyspnoea and of other symptoms of deficient aeration of the blood.

There are several points of interest in connection with the physical signs presented by this case, such as the shifting dulness at the posterior part of the chest, and the very remarkable tympanitic quality of the percussion-note on the left side anteriorly. The shifting dulness posteriorly was, of course, dependent upon congestion changing from one side to the other, according to the patient's decubitus; but the peculiarity of the percussion-note in front cannot be so readily explained.

The tympanitic resonance became marked a few

days after the patient's admission, and shortly before his death it exactly resembled that of pneumothorax. The left lung, as will be seen from the notes of the post-mortem examination, was generally solidified, and contained a good many minute excavations, but there was no evidence of there having been air in the pleural cavity.

I have frequently been surprised, in percussing over the anterior part of a pneumonic lung, to find a clear but high-pitched sound brought out, and this in cases where the lung was solidified throughout; but I have never before met with an instance in which there was amphoric resonance in connection with consolidation. It would have been quite impossible, in a case like the present one, to have diagnosticated the development of tuberculosis. The temperature-record shows a marked evening exacerbation, which is usual in acute phthisis, but the reverse of what happens in acute tuberculosis, and the general symptoms might all have belonged to the former disease. That these two diseases are essentially distinct, and that a differential diagnosis can be made, I think any one may be convinced of by reading the report of two very interesting cases by Dr. Hutchinson, in the *Medical Times* for March 1, 1872. In the one disease there is an acute alveolar catarrh, the products of which undergo rapid caseous metamorphosis and lead to destruction of the pulmonary substance. In the other there is a sudden development of miliary tubercles in the lungs, followed by an active catarrhal process, and occasionally, though less frequently than in acute phthisis, by pulmonary excavations. Both diseases run a very rapid course; but this is particularly true of acute tuberculosis, which has been known to terminate in two weeks. In regard to the differential diagnosis of the two diseases, the points of distinction that are especially prominent are those relating to the temperature-records and the relation that the general symptoms bear to the physical signs. The temperature is considerably elevated in both, and a daily exacerbation takes place in both, but, as already stated, it occurs in acute phthisis in the evening, and in acute tuberculosis in the morning. The general symptoms of acute phthisis may nearly always be accounted for by the physical signs, but the two are markedly disproportionate in acute tuberculosis; so much so that it is frequently confounded with other acute diseases, particularly typhoid fever.

As an instance of this great disproportion between the two sets of symptoms, I may mention the following case:

In June, 1874, a colored barber, 22 years of age, whom I had been in the habit of seeing frequently, and of whose previous history I therefore knew something, consulted me in regard to a slight dry cough, and a feeling of malaise, accompanied by loss of appetite and so-called biliousness. I examined his chest, but was not able to detect any abnormal sign, and finding, on inspection of the throat, that there was a good deal of follicular enlargement, I concluded that this was the cause of the irritative cough, and that it was connected with the symptoms of constitutional depression.

I prescribed for him accordingly, but a few days afterwards he again came to see me, and I was at once struck with his altered appearance. He had high fever, and was so weak and was suffering so much from dyspnoea that he could scarcely cross the room without fairly panting for breath. His cough had also somewhat increased, but it was still unaccompanied by expectoration. Examination of the chest revealed universal enfeeblement of the respiratory murmur, but there was no dulness anywhere, and there were no adventitious sounds to be heard. The case, of course, resembled very closely one of typhoid fever, but, taking into consideration the absence of intestinal symptoms and a known hereditary predisposition, I diagnosed acute tuberculosis. He was removed to the country, and died eight or nine weeks after the commencement of his illness. No autopsy was made, but, from what I afterwards learned of the progress of the case, I feel sure that the diagnosis was a correct one.

ON THE MISINTERPRETATION OF APPEARANCES UNDER THE MICROSCOPE.

BY CHARLES STODDER, ESQ.,

Boston, Massachusetts.

Read before the Biological and Microscopical Section of the Academy of Natural Sciences, and recommended for publication in the Philadelphia Medical Times.

ALL text-books caution novices against misinterpreting what they see, or think they see, in their microscopes. Experience teaches that the caution is needed even by many who have long used the instrument. Objects viewed by transmitted light are seen under such different conditions, and the light received by the eye has been subject to such entirely different influences, from those that affect ordinary vision, that these conditions and influences must be carefully considered in forming any conclusion of the structure of the object studied.

A thin, plain plate of any homogeneous substance, such as silica or glass, is as invisible as air. Let the plate be curved or corrugated, or vary in thickness, and it becomes visible. Why? Not from any change in its nature, but because of its action on light. It both reflects and refracts; consequently, different and varying intensities (and colors, unless homogeneous light is used) reach the eye, and thus render visible the corrugation or inequalities of the thing under investigation. Every particle of matter not absolutely opaque acts on transmitted light as a lens, or prism, or group of minute prisms, no matter what its size or shape. Every one of the most minute specks of matter acts as a lens, and presents to the eye, under a certain magnification and focal adjustment, the appearance of a dot, bead, or spherule. The combination of two curved surfaces will act as a lens, and show beads where none exist in nature. This fact I announced many months ago. I send with this for the Section a slide of diatoms, from Bodington, Maine, among them numerous Pinnulariæ of several species (so called). Occasionally two frustules will be found lying across

each other, the costæ of one crossing the other at some angle. I have made (in my unskilful way) a sketch of one such instance, to which I will call your attention. The costæ are smooth and clean. Wherever those of the two frustules intersect each other (at nearly a right angle) we see rows of distinct, apparently spherical beads, but the evidence presented in the four directions on every side is conclusive that no beads exist there,—that what we actually see are “ghost beads:” an optical effect, and the result of the passage of light through a transparent refracting medium with curved surfaces. Numerous other examples similar to this are to be found on this slide.

Now, does not this present strong evidence that the so-called beadings seen in scales of insects, about which so much has been written, are also optical effects? So, too, of the “beading” of many of the diatoms.

Dr. Woodward, of Washington, has made a photograph of *Surirella gemma*, showing the whole surface broken up into beads, or dots,—an appearance that can be obtained by proper management of the illumination, but which is not the true resolution. E. Hartnack published, a few years ago, his idea of this diatom, derived from his use of his very high powers. He described the appearance as “flat hexagons.” It is scarcely possible to conceive that he could have taken Dr. Woodward’s beads for hexagons; so it is only a reasonable inference that he (H.) saw something else. It is well known of that diatom that between the strong, sharply-marked costæ there is a set of fine transverse lines; but crossing these at right angles is a set of *very* fine longitudinal striæ, which can be seen only with a good instrument and with very careful management of the illumination. When these are in sight the transverse lines are *absolutely invisible* with the very best glasses; and with the best it can be demonstrated that Hartnack’s “flat hexagons” have no existence, and were a theoretical explanation. The longitudinal striæ are not continuous, but interrupted at frequent intervals. This may be owing to the inequality of the surface of the plant. I explain the appearance of the dots or beads as caused by the intersection of the two sets of striæ on different planes with each other, so illuminated that the light is partly received from each. If true beads existed as represented in the photograph, it is difficult to conceive of any illumination that could cause them to disappear. The study of other genera of the Diatomaceæ only confirms me in this opinion. *Navicula cuspidata* Kutz is a well-known form, described as having “very fine transverse striæ.” My friend and correspondent J. E. Smith, of Ashtabula, Ohio, discovered that this species has exquisitely fine longitudinal lines also. By certain illumination this may be made to show “dots.” Examined with a one-fiftieth, I demonstrated conclusively that the two sets of striæ are on different planes, either of which could be brought into focus *without the other*. That there are a vast number of species of diatoms with true “beads,” I admit.

I send a slide from mud bottom of Great Herring Pond, Cape Cod, obtained several years ago by officers of the United States Coast Survey. This material supplies an abundance of *Stephanodiscus Niagara* Eh.,* first found by Prof. J. W. Bailey at Niagara Falls. This species presents fine examples of true dotted or bead structure, and the contrast is very great (under a high power and good definition) with the optical beading, though under other conditions, and without warning, the differences are easily overlooked.

Too many histologists have a poor opinion of the study of diatoms; but errors in the interpretation of their appearances illustrate the errors that may, and do, occur in the study of other subjects, while, so far as is yet known to science, the Diatomaceæ afford by far the best material known for the study of the instruments. The lenses that will best show the most minute structure of a diatom may, *a priori*, be taken to be the best to exhibit the most minute "lines and dots" that make up the aggregate of all structures; and I believe the experience of histologists who have used a large variety of instruments will confirm this. The one who has used only a very few lenses in the course of years, though he may be most accomplished in his own specialty, and be able to do more and better with his own lenses than any one else can with them, is not competent to make comparisons or judge of the value of other lenses in his own work, until he has actually worked with them.

TRANSLATIONS.

ACTION OF ESERINA IN CHOREA.—Dr. E. Bouchut (*Bull. Gén. de Thérap.*, April 13) records the results of four hundred and thirty-seven observations upon the action of eserina (the active principle of calabar bean), particularly in the chorea of children.

He finds that this alkaloid, while diminishing muscular contractility, augments that of the smaller vessels. It may be employed hypodermically or by the stomach, and should be given fasting. It may be given hypodermically in the dose of one-twentieth to one-twelfth of a grain, and, as its effect only lasts one to three hours, the dose may be repeated until one-fourth to one-third of a grain is given in twenty-four hours.

The effects of eserina are observed within a few minutes from its administration, and these are constant in the dose of one-twentieth to one-twelfth of a grain. It usually produces paleness, with contraction, occasionally followed by diminution of rate in the pulse. Nearly all the children to whom eserina was administered experienced malaise, burning pains in the epigastrium, with gastralgia, nausea, and rejection of stringy sputa.

Eserina occasionally causes bilious vomiting; it does not modify the temperature sensibly. In the doses above mentioned, eserina never produces colic or diarrhoea. Given internally, it usually produces no effect upon the pupil. It frequently causes profuse perspiration of the face and body. Paresis, and occasionally transitory paralysis of the diaphragm, are among the most serious and painful phenomena produced by this remedy.

* This same diatom is also abundant in the Toome Bridge, Ireland, deposit (fossil?), though the books do not mention that it has ever been found in Europe.

When the action of the eserina is spent, the patients return to their normal condition, and the substance does not seem to have any consecutive effect. It is not found in the urine, at least after administration in these small doses. Given in chorea, eserina arrests the movements while its effects last, and moderates them little by little in the intervals, so that this disease is cured, on the average, in about ten days. The effects of the remedy are more certain when it is given hypodermically.

Dr. Bouchut has never seen tremor or convulsions produced by the use of eserina, and thinks it probable that these symptoms are not likely to be brought on unless where the remedy has been employed in large and toxic doses.

X.

OPERATIVE PROCEDURE FOR THE EXTRACTION OF TUMORS OF THE MAXILLARY SINUS.—Dr. Armand Després remarks (*Bull. Gén. de Thérap.*, April 15) that no rule has ever obtained in operations upon this portion of the body, each surgeon following that plan which has seemed most fitting in any given case. After giving the methods of several surgeons for opening the sinus to extract an exostosis, Dr. D. gives the following as performed by himself:

An incision is made, extending from the inner angle of the eye at the insertion of the orbicularis tendon down the side of the nose, following the contour of the ala, and, when the naso-labial sulcus is reached, extending downwards along this to its termination, care being taken not to penetrate the mouth. The bone is then laid bare, the periosteum-cutaneous flap being carried back until the malar tuberosity is attained.

The ascending process of the maxillary bone is then divided, by means of cutting-forceps, from the edge of the nasal fossa to the lachrymal sac. Then the anterior wall of the maxillary sinus is divided by transverse incision, just under the malar bone. Raising the bone then, by the aid of a lever, it breaks off on a level with the edge of the orbit and the malar tuberosity. The bony fragment, pentagonal in shape, is then removed, and the tumor, which may be easily gotten at, is removed, either whole or piecemeal, according to its size. The cutaneous incisions cut the nasal branch of the facial artery, and the suborbital artery; they may be ligated if it is thought desirable, but simple pressure often serves to arrest the hemorrhage. There are no other difficulties in the process; section of the bone with the cutting-forceps is easily performed, and pressure causes it to break evenly at the diseased point. Silver wire sutures may be used alongside the nose and at the ala, while the twisted suture is to be employed to unite the naso-labial sulcus. Illustrations are given by Dr. Després, showing the very slight scar which remains subsequent to the operation.

GALVANO-CAUSTIC TREATMENT OF NEW GROWTHS, ETC., IN THE AUDITORY MEATUS.—Dr. L. Grossmann contributes a series of papers on this subject to the *Wien. Med. Presse* (Nos. 11, 12, 14, and 15, 1875). He believes this method to be much better than either of those formerly in use—the knife or caustic—for the removal of fibrous polypi in the external auditory meatus. Perforation of the tympanum by this method is also, Dr. G. thinks, preferable to either myringotomy or myringectomy, since an opening can be made as large as is desired, with such rapidity as to cause almost no pain.

This operation presents peculiar advantages for the removal of foreign bodies from the external meatus when the usual means, by a stream of water, etc., have failed. In addition, loss of blood and the effects of reaction are also avoided. The pain caused by the glowing wire is not so great nor so lasting as that experienced in operations by the knife.

Finally, it is possible to reach by the galvano-caustic wire localities which cannot be attained by other instruments, and the wound made by this requires no subsequent dressing. X.

CRAMP OF TELEGRAPH-OPERATORS.—M. Ominous contributes an observation on this affection to the *Gaz. Méd. de Paris*, April 10. After alluding to the cramp due to repeated movements of certain muscles, and observed not only among writers but also among designers, engravers, and musicians, he gives a case of a similar character occurring in a telegraph-operator.

The patient, who had used the Morse instrument for nineteen years, first noticed a difficulty in making the dots, and especially a succession of dots. The first letters which he found difficulty in forming were *l*, which is indicated by three dots, *z*, which is indicated by two dots, and *u*, which is indicated by two dots and a line. *D*, which is formed by a line and two points, he found easier, because the first movement finishing the line gave greater assurance of movement. Soon it became impossible to make dots at all by the ordinary manipulation, and the patient then had recourse to his thumb, which he used for two years. At the end of that time the thumb was seized with cramps, and he then had recourse to the index and medius successively. Each of these was used two or three months, and then became useless on account of cramp. Even the use of the wrist, which he finally resorted to, gave rise to trembling in the fore-arm, and at last to the same symptom in the leg of that side, as well as pain in the neck, and sometimes vertigo and insomnia. The only method of relieving these symptoms is to change the instrument employed, using that known as Hughes's, and alternating this with Morse's. X.

THERAPEUTIC NOTES.

IN RHEUMATISM.—

R Trimethylamini, ℥iv ad ℥viiij;
Syr. zingiberis, ℥i;
Aq. menth. pip., ℥i.—M.

Take at intervals of one to three hours until pain is relieved.

FORMULA FOR THE ADMINISTRATION OF CROTON-CHLORAL HYDRATE.—

R Croton-chloral., gr. xxx;
Glycerinæ, ℥iiss;
Ext. glycyrrhiz., ℥i;
Aq., et syr. simpl., āā f℥iiss.—M.

Tablespoonful *pro re nata*.

PILLS OF THE ABOVE.—

R Croton-chloral.,
Pulv. glycyrrhiz.,
Confect. rosarum, āā gr. xv.—M.

Ft. in pil. no. xx.

IN PITYRIASIS.—

R Ol. theobromæ,
Ol. ricini,
Ol. amygdalæ, āā ℥v;
Hydrarg. sulphat. flav., gr. xv.—M.

LOTION IN ERYSIPELAS.—

R Camphoræ,
Acid. tannic., āā ℥i;
Etheris, ℥i.—M.

Bathe the parts adjoining the diseased skin every two or three hours, or oftener.

DIARRHŒA MIXTURE.—

R Olei ricini, ℥xxiv;
Sp. chloroformi, ℥iiss;
Sol. morphinæ mur., ℥i;
Pulv. gum. acaciæ, ℥iiss;
Syrupi, ℥ss;
Aquæ, ad ℥iv.—M.

A dessertspoonful every hour and a half until the bowels are quieted.

PURGATIVE IN DYSPEPSIA ACCOMPANIED BY CONSTIPATION.—

R Mass. hydrarg.,
Ext. colocynth. comp., āā gr. xxx;
Pulv. ipecac., gr. iii.—M.

Ft. in pil. no. xii.

Two of these are to be taken every second or third night, and followed by a Seidlitz powder the next morning.

CHLORAL SUPPOSITORIES.—The production of a chloral suppository containing a sufficient proportion of this drug to cause sleep has heretofore been deemed impossible. M. H. Mayet, pharmacien, of Paris, has, however, devised the following formula, by which he manages to get forty-five grains of chloral in each suppository:

R Ol. theobromæ, gr. xxx;
Cetacei,
Pulv. chloral., āā gr. xlv.

For one suppository.

These suppositories are of good consistence, and may be easily put into use.

INJECTION FOR CYSTITIS.—

R Sodii hyposulphit., ℥iv;
Aq. destillat., lb. i, ℥iv.—M.

This solution may be employed in five injections, in chronic catarrh of the bladder, when there is pain and the carbolic acid injection cannot be employed.

LOCAL ANÆSTHETIC.—

R Pulv. camphoræ, ℥iiss;
Ætheris sulph., ℥v.—M.

Rub into the skin for a few moments at the locality where it is desired to produce anæsthesia.

IN DIPHTHERIA.—

R Pulv. cubebis,
Aq. menth. pip., āā ℥v;
Syr. aurantii flor., ℥vii;
Aquæ, ad f℥iv.—M.

One or more tablespoonfuls for an adult, every three or four hours.

ANTI-GASTRALGIC DROPS.—

R Tinct. nucis vomicæ,
Tinct. castorei, āā ℥ss.—M.

Two drops during the paroxysm, in half a wineglass of infusion of chamomile.

CAMPHOR OINTMENT.—

R Pulv. camphoræ, gr. xv;
Glycerinæ, q. s.;
Axungiæ, ℥i.

Useful in erythema and in vesicular and squamous affections of the skin.

GARGLE IN SYPHILITIC ULCERATIONS.—

R Hydrarg. chlor. corros., gr. ii;
Glycerinæ, ℥iv;
Aquæ, ad f℥viii.—M.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

EDITORIAL.

OWING to the length of the letter which we print from our correspondent at the meeting of the American Medical Association, we lessen to-day our usual quota of editorial matter.

THE meeting of the American Medical Association just closed appears to have been socially a very successful one, there having been a large number of delegates in attendance, and a universal spirit of fraternity and good feeling having prevailed. The presence of a large delegation from Boston was a novel and praiseworthy event. This delegation, we happen to know, went home in a state of great satisfaction with their trip; so that it is to be expected that the effort of our Eastern brethren will not be a spasmodic one, but that hereafter New England will always be well represented. The delegation from Philadelphia was, unfortunately, a small one; but, as it was headed by Dr. Gross, it played a fairly prominent part in the sessions of the Association.

WE notice in this week's *Chicago Examiner* "The New Scriptures according to Tyndall and Others," taken from the *Canada Lancet*. The travels of this *jeu d'esprit* have been somewhat remarkable. Originating in Cincinnati, it was copied, some months since, from our columns into the *British Medical Press*. After a sufficient length of time, it reappeared in Canada, "from one of our transatlantic contemporaries," and has at last reached Chicago. We commend the *Medical Examiner* as a live paper, dealing in the freshest intelligence.

CORRESPONDENCE.

LOUISVILLE, May 6, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Although it appeared to be your desire for me to report the proceedings of the American Medical Association in regular form, yet I have found so little formal material of general interest and importance, and so much of outside matter, that I beg to offer my account in the shape of a letter.

On Monday evening the Association of the Medical Editors of the United States met in a parlor of the Galt House. The exact aims or advantages of this association are as indefinite as the outlines in a London fog or in the smoke of the Louisville bitumen. On the present occasion, Dr. Edgar, of St. Louis, the President, read an address, which was simply the best thing of the sort I have ever had the pleasure of listening to, and which I hope will be re-echoed by the medical press throughout the length and breadth of the land. The subject of his remarks was medical advertising; not so much the forms of it which are met with in the East, as the far more rank and noxious methods which, it appears, can only be produced upon the rich soil of a comparatively new country.

Nothing that the *Times* has ever said portrays in as dark but true colors the utter hopelessness of the present organization of the profession in this country as does the following sketch which Dr. Edgar drew of the way in which medical schools spring up in a night, like deadly fungi:

"A dozen or fifteen or twenty doctors, more or less, meet and organize themselves into a medical faculty; a charter is procured, and the chairs 'panned out' among them, and circulars scattered thick as black-birds in autumn, heralding the wonderful advantages of this new school. A card is in all the publications of the city, secular and scientific; thus no means are spared to make known that Prof. A. has the chair of obstetrics, and Prof. B. that of surgery, etc., to the end of the list; then come as many more names (with their addresses) as assistant lecturers, waiting to don the discarded mantles of their superiors. In this way, twenty-five or thirty doctors are advertised into practice over their neighbors, often every way their superiors (except, perhaps, the teacher of chemistry, who has to be paid, as the public have little use for his wares).

"Other professional men, observing the success of this shrewd trick to inveigle the public, and seeing no other way to keep even in the race, organize another school, and the community is startled by the announcement of as many more professors in medicine, born in a day. Thus a city of a hundred thousand inhabitants may boast two, or perhaps three, medical schools, equipped, and in full blast, with large classes, where fifty properly qualified students it might be difficult to find. By 'beating the brush' in all directions, and offering all admission who apply, with or without education, with or without money or price, large classes are collected; and, if the graduating list of either school is not quite

satisfactory (on account of the nine months' short cut), there is generally timber enough at hand, none the worse for having been used, half a dozen or more 'adeundems' are added, and the bill is filled, the effect upon the public satisfactory, which, of course, is the end sought."

The President of the Association then at length discussed the effects of this practice upon the profession in the United States; but the utter ruin of professional *esprit de corps* and culture, the bitter discords, the vast hordes of uneducated men, which are the necessary fruit of such sowing, need no advertising to be known. Only those who see the results of this system close at hand can, however, appreciate the magnitude of the evil; but the fact that, instead of the dozen schools required to supply the natural demand of the country, there are about one hundred, may give some idea of the necessity for reform. I may mention, *en passant*, that in Cincinnati alone there are six medical schools of various character; that in Louisville a "spring course" enables a man to graduate in nine months (of study?); that in the same city the lectures are practically free, in that a "free scholarship" is offered for every State Senatorial district in the South; and that in Mobile and Charleston the tuition is offered absolutely without cost.

Under the shadow of these institutions the great West is overrun with the men who are rather John the Baptists for the undertaker than the enemies of that necessary evil.

Dr. Edgar may or may not be correct in asserting that at present "the facts are fast becoming known throughout the civilized world, and America is fast becoming the promised land for the quacks and impostors in medicine of the world. The men who fail to pass the Government boards for license, either in Europe or South America, flock to the United States for an open field." But certainly the evil tidings must continually spread more and more, and more and more reap destruction for the unfortunate people of these United States.

It is easy to denounce, but it is harder to prescribe a remedy; and the great merit of Dr. Edgar's address was that he did show most conclusively the true solution of the problem. His diction was so clear and his blows so direct that his very words were golden. After portraying the self-evident fact that the schools and the schoolmen must of necessity be opposed, as a rule, to any reforms in medical education, because such reform must render narrower the entrance to the profession, and must, therefore, wipe out entirely many of the schools, and lessen the value of others as advertising mediums, Dr. Edgar says,—

"Some doctors profess to believe that 'as the masses improve so will the average doctor,' that the supply will meet the demand; than which a greater fallacy was never conceived. Is not the average intelligence of the masses in the United States equal at least to the masses of Europe? Yet the doctors of this country do not compare with those of the European States in general culture or medical acquirements. Let no one deceive

himself; in every country where the doctor stands high, the entrance to the profession is guarded by a State Board, not instituted to protect the doctor against quacks, but to protect the community against incompetent doctors. The practice of medicine and surgery has been so far monopolized in the cities of this country by the schoolmen that every doctor is brought to believe that it is indispensable to a good paying practice to be advertised as a professor in a medical college."

The remedy which Dr. Edgar proposes, and which is evidently the only possible one, is the formation of State Examining Boards; a diploma from which shall be necessary for the practice of medicine in the various States. Your readers will remember that the *Times* has already advocated this plan, but never with the force and persistency it deserves. It would occupy too much of your space to follow Dr. Edgar through the further details of his address, but I would call attention to one fact already hinted at, but which he insists upon and makes very clear,—namely, that the opposition to the formation of State Boards comes from the professors who do so abound. Many of these gentlemen talk about the "needs of poor communities," "vested rights," and what not; tack on to bills amendments seemingly fair, but really fatal in their character, or by various devices seek to maintain the present system,—all of which, coming from men whose interests are at stake, deserves only the answer given by the goat to the fervent public prayer of the hypocrite—Bah! After all, however, the whole profession is not as yet entirely resolved into college faculties, and it is to be hoped that the outside profession will place upon medical teachers the restraining influence of a stern public opinion, and will watch most narrowly the course of that portion of the medical press which is bound hand and foot to the Delilah of school interest, and, if need be, take measures to enlighten the laity, whose dearest interests are at stake, and who must be the final arbiters in the matter.

Singularly diverse from this clear solution of the present problem was the extraordinarily wild and impracticable proposition made by the President of the American Medical Association, in his opening address. He proposed "that it be solemnly resolved by this meeting that it shall be regarded as derogatory to the character of any physician, in any part of the United States, to take under his care, as a student of medicine, any one who cannot exhibit evidence of having taken a degree in a regularly-chartered college, or a certificate of qualifications, necessary to become a student of medicine, from a Board of Examiners appointed for that purpose by the American Medical Association."

A committee was appointed at the last session of the American Medical Association to report "on what legislative action, if any, can be taken to enforce by law an examination of all persons who enter upon the practice of medicine and surgery, by a State Board of Medical Examination," regardless of diplomas; and it is to be hoped that they will show some wisdom in making that report. The only thing the Association can do is to call the attention of the State Societies to the subject of

State Examining Boards, and to urge upon them the necessity for immediate action.

The President's address, on the whole, was a good one. He began by calling attention to the objects for the furtherance of which the Society was first organized. These objects were as follows. *First*, To give emphatic expression to the views and aims of the medical profession in this country. *Second*, To supply more effectual means than have hitherto been available here for cultivating and advancing medical knowledge. *Third*, To elevate the standard of medical education. *Fourth*, To promote the usefulness, honor, and interest of the medical profession. *Fifth*, To enlighten and direct public opinion in regard to the duties, responsibilities, and requirements of medical men. *Sixth*, To excite and encourage emulation and concert of action in the profession. *Seventh*, To facilitate and foster friendly intercourse between medical men. *Eighth*, To take cognizance of the common interest of the medical profession in every part of the United States.

Dr. Bowling then sketched discursively the extent to which these intentions had been carried out, and the difficulties that had been met with. The most interesting part of his address was that which detailed the fierce fight that has been waged between the Association and the medical schools, commencing almost with the infancy of the organization, rising into a great storm at Nashville in 1857, and ending, according to our President, last year, in Detroit, by the expulsion of the representatives of the schools from the Association. It is, however, evident that the battle is not yet over; and it is to be hoped that the Association will never cease its efforts till the heel of the law is placed upon the medical colleges whose unbridled license has been the curse of the profession and the bane of the people.

To expect the address of a President of the American Medical Association not to contain untrue flattery of the American profession is to fly in the teeth of the traditions of the elders; but it would be far better if the truth were told, that, skilful as our practitioners are, yet to the higher thought and knowledge of the world we have contributed almost nothing. Dr. Bowling is not, however, entitled to the least censure for conforming with orthodox usages and maintaining the patriotism of the Cross-Roads, by asserting, "that our own country has, during this period [the century], contributed as much to this development as any other, no unprejudiced observer will dispute." On the whole, considering the circumstances of the occasion, the various public writings of the President, and the many demoralizing examples which exist, Dr. Bowling is entitled to great credit for the moderate and gentlemanly tone of his address.

Yesterday morning Dr. A. H. Daud, General Secretary of the Canadian Medical Association, was presented to the meeting as a representative of the sister body. After his speech of thanks, a tall Texan, with a voice whose stentorian tones hushed all to silence, "declared that he could only wish to Dr. Daud and his people the same good luck which had happened to his

State, namely, to be annexed politically, socially, and professionally to the great American Republic."

The desire was exceedingly well "put," and brought rounds of applause. The humorous Texan is certainly a man of refreshing and most praiseworthy originality. According to his statement before the Obstetric Section, he came to Louisville upon a mission. Japhet was in search of his father, but he was in "search of a pessary for his daughter."

Dr. Gross, by special permission, read an address on "The Lost Arts in Medicine." Dr. Gross shares with Dr. N. S. Davis, of Chicago, the favor of the Association. Indeed, between them they may be said to have a builder's lien upon the organization. The influence which Prof. Gross wields appears to be due largely to his magnificent and richly-deserved surgical reputation; whilst Dr. Davis atones for his lack of this overpowering reputation by his close attention to the Association, his intimate knowledge of its regulations, and the clear-headed manner in which he directs its deliberations. It is stated that he has not missed a meeting for twenty-five years. Dr. Bowling is precluded by his age from actively presiding, and the gentleman who rules for him appears to have but little knowledge of the proper methods of ruling. If it were not for the constant interposition of Dr. Davis, the procedures would seemingly be very chaotic. When Prof. Gross offered to read his address in the general session, no one seemed to have any knowledge of the existence of any by-laws upon the subject; but when some comparatively obscure individual presumptuously essayed to follow in the wake of the great man, it was very instructive to see Dr. Davis, in his ringing, impassive, and implacable tones, call the attention of the meeting to the fact that the by-laws ordered that all volunteer addresses should be referred to their appropriate Sections.

The address of Dr. Gross was really a plea for the use of blood-letting. He reprobated in the strongest terms the present total abandonment of the practice, and entered at length upon the consideration of the causes which have led to it. The peculiar power of Prof. Gross was of course apparent in the address; but when he discoursed most closely upon therapeutic points, the well-known truth that surgeons rarely have clear and just ideas of medical therapeutics was very apparent, and the old saying of *ne sutor ultra crepidam* no doubt flashed across the inner consciousness of many of his auditors. To classify together aconite, digitalis, and veratrum viride is certainly almost to commit the unpardonable therapeutic sin. The proposition which Prof. Gross maintained, that bleeding has been too universally abandoned, is undoubtedly correct, but the assertion of the value of the remedy in such diseases as chronic phthisis, cholera infantum, and "even anæmia," is assuredly at variance with all the established facts of modern pathology and therapeutics.

The learned professor probably had in his mind the fact that exaggeration on the part of an orator is often necessary to bring the audience up to the proper level.

A palpable influence upon medical practice will, we doubt not, be perceptible in the journals of those sections of the West where the name of Gross is almost that of a demi-god. As we heard affirmed by one of the most eminent of the Western practitioners, the address will probably do a great deal of harm, and even cost a good many lives; but if our venerable representative has succeeded by the audacity of his statements in resuscitating venesection, humanity will, probably, be in the long run indebted to him, for the mode of treatment will no doubt soon settle to its true position.

The address of Dr. Austin Flint, upon the "Advances of Practical Medicine," of necessity contained nothing that would be new to the readers of a live journal like the *Times*, but it was a very well-digested, scholarly *résumé* of progress, and, as it was well delivered, riveted the attention of the body.

The only portions of to-day's (May 6) proceedings worthy of notice were the addresses of the chairmen of the Surgical and Obstetrical Sections. Dr. Moore, of Rochester, read an exhausting and exhaustive essay upon "Transfusion." It is a matter of profound wonderment that human nature on the platform is habitually so utterly unappreciative of and tyrannical to human nature on the benches, especially as the benches in the long run usually wreak sufficient vengeance upon the platform. Dr. Moore thoroughly wearied out his auditors, before he came to the interesting portion of his essay, by a long encyclopædic review of the literature of the subject,—a *résumé* which after all was no more complete than various articles which have appeared in the journals. When, however, the doctor did strike the ore-vein, the lead was a rich one. Several interesting cases of transfusion were reported, but offered nothing absolutely new except in the mode of operating. In this, however, it may be that Dr. Moore has made a very decided step in advance. As is often the case, although his theory is unproven, and probably false, its fruits in the efforts to which it has led have been very good.

As is well known, blood exposed to the air coagulates in a very few minutes. Dr. Moore believes that before the blood has been rendered unfit for use by actual coagulation there is a period at which its vitality is enormously impaired. It is, however, well known that blood which has some time previously actually undergone coagulation has been used hundreds of times in transfusion with the best of results. It therefore appears to be a pure assumption that in coagulation the vitality of the blood is lost, and it is much more improbable that before coagulation any change occurs. Moreover, there are two known tests of the life of blood,—*i.e.*, the movements of the white blood-cells, and the power of the red disks to absorb oxygen; and even long after coagulation both white and red corpuscles still give evidences of full functional activity.

The theory of Dr. Moore, true or false, impressed him with the idea that immediate transfusion is the proper method, and that the saving of time during the operation is of the utmost importance, and led him to

adopt the following method. A cylindrical india-rubber bag, about five or six inches long, and capable of holding as many ounces of blood, is to be provided. At its lower extremity it is to be closely attached to one arm of a canula having two arms at right angles to each other; the free arm of the canula is to be inserted into the vein of the receiver, the cephalic vein just above the bend of the elbow being the best, because straightest and allowing most readily the admission and retention of the canula. In inserting the canula, Dr. Moore exposes the vein by an incision about an inch in length, tears away the connective tissue with the blunt end of a coarse sewing-needle, and passes a narrow tape under the vessel. The vein is now clipped with a pair of scissors, according to the method of Nélaton, so as to make a valvular opening, into which the canula is inserted for three-quarters of an inch, and the tape tied around it. The donor and receiver are now placed side by side in such a position that the hand of the latter rests upon the lap of the former, whose arm in turn is extended across and above that of the receiver; an india-rubber funnel having been provided, the vein of the tightly-banded arm of the donor is opened by a free incision, and in the first gush which pours into the funnel, whose point is at the bottom of the bag, all the blood that is needed is usually received. Instantly the operator, who stands behind and between the parties, cuts the bandage, claps a compress over the wound, and bends sharply the arm of the donor upon itself. In this way he arrests the hemorrhage instantly, so that the man may stand aside. The operator now stretches upwards the cylindrical bag, previously supported by an assistant in front, doubles the free end shortly on itself, and rolls over and over the fold thus formed along the little bag so as constantly to force the blood into the vein. Dr. Moore insisted especially on the rule of *not compressing* the bag, but of allowing its elasticity to supply the motor power to drive the blood into the vein. He states that he had operated in the method just described successfully in forty-two seconds, and believes that fifty seconds is an abundant time.

The address of Dr. Byford was upon the use of injections of ergotin in uterine fibroid. The essay was a very thorough and creditable one, but contained reports of so many cures at the hands of his Western confrères that a very learned gynæcologist who sat near the writer suggested that some of the results were probably due to the difficulties of diagnosing between phantom tumors, localized peritoneal exudations, and true fibroids. Some of the cases were seen by Dr. Byford himself, and are, therefore, scarcely open to suspicion; but it would require careful consideration from a very able gynæcologist to form a fair judgment upon the value of his evidence. As your correspondent's studies of this branch have been pretty much limited to discovering the best form of a speculum and the best methods of introduction of the same, he consigns Dr. Byford to the tender mercies of that "white-livered Philadelphia grammarian" who in time past was so successful in improving his literary productions.

The address upon State Medicine was to have been read to-day, but the grievous prolixity of Dr. Moore forced the postponement of Dr. Bowditch's address until to-morrow.

The delegates of the Association are now all in, and it is possible to form an opinion as to the *personnel* of this year's meeting. There are nearly five hundred in all, representing the following States and Territories: Alabama, Arkansas, Colorado, Connecticut, District of Columbia, Florida, Georgia, Illinois, Indiana, Iowa, Kentucky, Maine, Maryland, Massachusetts, Michigan, Minnesota, Mississippi, Missouri, New Jersey, New York, North Carolina, Ohio, Pennsylvania, Rhode Island, South Carolina, Tennessee, Texas, Virginia, Wisconsin.

I believe it is generally conceded that the men are more than usually representative. Boston is especially well represented by such men as Drs. Bowditch and Clark, Dr. Bixby, an old partner of Dr. Storer, and Dr. Chadwick, the secretary of the district medical society; New York has some men of prominence, such as Flint, Sims, Sayre, and Jas. R. Wood; and Philadelphia has a small delegation headed by Gross and Atlee. Probably to the superior character of the delegates are owing the grave decorum and general good feeling which have characterized the deliberations of the Association.

Numerous papers have been read in the various Sections, some of them excellent, many of them feeble, and not a few absolutely puerile. It is bad enough to have gentlemen, who mistake themselves for great luminaries, reflect very glimmeringly but very lengthily the light of ancient text-books, but assuredly some one should hold to a stern reckoning those officers of sections who allow this unmerciful persecution of the members who attend. The law clearly requires that no papers shall be introduced which have not been submitted to the Secretary a month prior to the meeting, and approved of by him after examinations. Loud complaints concerning the Obstetrical Section have especially been made. But, from what I have seen, I do not believe that this Section has been as badly afflicted as some of the others.

The Nominating Committee have selected Philadelphia as the place of meeting next year, and Dr. Sims as President. Drs. Drysdale and Frické, it is whispered, are to replace Drs. Stillé and Murray Cheston on the Publication Committee.

J. Marion Sims was born in Lancaster district, South Carolina, January 25, 1813. He graduated at the University of South Carolina, situated at Columbia, in 1832; subsequently attended medical lectures in Charleston; and in 1835 received the degree of doctor of medicine from the Jefferson Medical College of Philadelphia. Dr. Sims began his professional career with Dr. W. O. Baldwin, of Alabama, in and around Montgomery, they being friendly contemporaries rather than partners or rivals. He acquired a high reputation in the treatment of diseases of the uterus and injuries to females while in Montgomery, and there established a private hospital for females. In 1853 failing health caused Dr.

Sims to leave his Alabama home and locate in New York. Previous to his removal he married a daughter of Dr. B. Rush Jones. His career in New York is well known to the profession. In 1861 he left the United States, and did not return until 1868. During this period he practised medicine in London and in Paris.

The Association has been very handsomely entertained during its stay by various citizens, and Dr. Edward Richardson, Chairman of the Committee of Arrangements, deserves great credit for the manner in which the work has been performed. It is said that the profession at Louisville is very much divided by bitter feuds, but on the surface all has been as placid as a summer day. The Convention does not close until to-morrow, but very many of the delegates have already left the city.

Yours truly,

PONTIFEX MAXIMUS.

PROCEEDINGS OF SOCIETIES.

BIOLOGICAL AND MICROSCOPICAL SECTION OF THE ACADEMY OF NATURAL SCIENCES.

MARCH 1, 1875.

DIRECTOR W. S. W. RUSCHENBERGER, M.D., in the chair.

PRESENT, Messrs. Neill, Morris, Tyson, I. Norris, Holman, Pierce, Seiler, and Richardson.

The minutes of the previous meeting were read and approved.

An interesting article "On the Misinterpretation of Appearances under the Microscope," by Mr. Charles Stodder, of Boston, Mass., Corresponding Member of the Section, was then read by the Secretary. This paper pointed out very clearly certain errors into which a want of care and caution was liable to betray microscopists, and was admirably illustrated by some slides of mounted diatoms (donated by Mr. Stodder to the Section), one of which exhibited several rows of perfect beads, just where transverse striæ of two frustules of Pinnulariæ crossed each other nearly at right angles, thus proving that the beaded appearance, as observed by most of the members present, was merely an optical effect, the result of the passage of light through a transparent refracting medium with curved surfaces. (See p. 519.)

Dr. RICHARDSON remarked that it gave him great pleasure to see so much interest taken in the Section by the corresponding members, especially when this interest was demonstrated by the contributions of such elaborate and instructive papers as that which had just been read.

On motion, the article was referred to a committee composed of Drs. Tyson, Morris, and Richardson.

Dr. J. CHESTON MORRIS exhibited a specimen of Triceratium from Thames mud, which, under the one-inch objective, displayed hexagonal markings with both direct and oblique light, but with a half-inch lens, draw-tube, and high eye-piece, showed, by oblique illumination, small spines on a horizontal plane, demonstrating what Dr. Morris remarked he believed was the true structure of the diatom,—viz., that its surface was studded with minute cones, just as that of Pleurosigma angulatum is with bosses. Dr. Morris observed that this specimen he had on exhibition illustrated his remark at the last meeting, that whilst best results were in general to be obtained by central light, in some cases we

failed to perceive certain characteristics without the aid of oblique illumination. It also showed the advantage of "penetration" or "depthing," because with an objective possessing this quality in a low degree, and focussed for a plane in which lay the apices of the cones, we would see only small dots, although by approximating the lens to the object, larger dots, and on still further depression (so as to bring into view the plane on a level with the bases of the spines), a mosaic of hexagons, would become visible.

Dr. RICHARDSON inquired whether Dr. Morris had any evidence that these supposed hexagonal markings were not really optical illusions, produced by the close juxtaposition of circular dots, as pointed out by M. Nacet and exquisitely illustrated by a figure at the end of Dr. Carpenter's last (fifth) edition of "The Microscope and its Revelations."

Dr. MORRIS replied in the negative, and thought it quite possible that the bases of the spines were circular.

Mr. D. S. HOLMAN explained his method of investigating diatoms, etc., by rolling them over and over in the stream of liquid flowing along the narrow channel connecting the two chambers of his improved "Current Slide" (see *Philadelphia Medical Times*, April 5, 1873). Mr. Holman also showed a current slide carrying a fluid containing minute particles of gamboge in active molecular motion, and remarked that this molecular or Brownian movement, supposed by some to be due to external jarring of the instrument, was by this experiment indicated to be the effect neither of surrounding vibrations, nor of electricity, nor of a difference in temperature of the upper and lower enclosing surfaces of glass, but the result of some *inherent power* of the substance.

Dr. JAMES TYSON observed that he had in his cabinet a specimen of gamboge, mounted in fluid three years ago, which showed this curious Brownian motion in perfection for at least two years, at the end of which time he last examined it. He was at a loss to understand how Mr. Holman's experiment proved that the vibratory or jactatory movement, as it was often called, was not due to external influences, which might cause the tremulous motion of molecules of matter in the current, just as the waves of a river might rock a boat, even whilst it floated rapidly along in a swiftly-flowing part of the stream.

Mr. HOLMAN replied that if we shook or jarred the table on which the microscope stood, we could see that the molecules all moved in one direction, just as they did in the current upon his slide, and yet it was perfectly obvious that, besides their forward movement, these minute particles had an independent motion in cycloidal arcs around one another. Mr. H. added that in some of his specimens the Brownian movement had continued uninterruptedly for four years, and, so far as his investigations had gone, there was no substance incapable of exhibiting it; powdered emery, for example, displaying it very satisfactorily indeed.

SELECTIONS.

No. 55. *An Act to Regulate the Practice of Medicine, Surgery, and Obstetrics in the Commonwealth of Pennsylvania.*

SECTION 1. *Be it enacted, etc.,* That the standard qualifications of a practitioner of medicine, surgery, and obstetrics, or of any one who may attempt to practise, singly or jointly, medicine, surgery, or obstetrics, shall be and consist of the following—namely, a comprehensive and practical knowledge of human anatomy, human physiology, pathology, chemistry, *materia*

medica, obstetrics, practice of medicine and surgery, and public hygiene, and a good moral character.

SECTION 2. The possession of a diploma, regularly issued by a medical school acting under a charter from this or other State or country, shall constitute the sufficient license for the person to whom such diploma is granted, to practise, singly or jointly, medicine, surgery, or obstetrics, as set forth and empowered in said diploma: *Provided, however,* That a diploma that has been or that may hereafter be granted for a money consideration, or other article of value alone, or that has been or may hereafter be granted to any one who has not pursued the usual course of studies required by a legally chartered medical school, shall not be considered as a sufficient qualification under this act.

SECTION 3. Any practitioner who may not have a diploma, as provided for in section two of this act, and who may not be qualified, as hereinafter provided, shall have the privilege of applying to the prothonotary of the court of common pleas of the judicial district in which such applicant resides, for an examination in the branches of medical science and art set forth in section one of this act; whereupon it shall be the duty of such court to appoint a committee or committees, consisting each of three respectable practitioners of medicine of the school of practice recognized in this commonwealth, to which such applicant or applicants may profess to belong, and shall fix the time and place of holding such examination. Each of said applicants, before being admitted to examination, shall deposit with such committee the sum of fifteen dollars (\$15), which money shall be equally divided among them, for which they shall give a receipt; it shall be the duty of such committee or committees to convene at any time upon the call of an applicant or applicants for examination; it shall be the duty of such committee, when the said applicant is found to be qualified, as set forth in section one of this act, to grant to such applicant a certificate, and said certificate shall be the sufficient license for the person to whom it is granted to open an office in this commonwealth for the practice of medicine, surgery, or obstetrics; it shall further be the duty of such committee to appear before the clerk of such court and take an oath or affirmation that they have not taken and will not receive, directly or indirectly, any other compensation for instituting such examination than that which is herein provided.

SECTION 4. Any person who has attended one full course of lectures in any respectable school of medicine recognized by law, and has been a resident practitioner of medicine, surgery, or obstetrics in this commonwealth five years previous to the passage of this act, is hereby authorized to pursue the same. Any person who has been in the continuous practice of medicine, surgery, or obstetrics for ten years in this commonwealth shall be and is hereby authorized to pursue the same.

SECTION 5. Any person who shall attempt to practise medicine or surgery, by opening a transient office within this commonwealth, or who shall, by handbill or other form of written or printed advertisements, assign such transient office or other place to persons seeking medical or surgical advice or prescription, shall, before being allowed to practise as aforesaid, appear before the clerk of the court of quarter sessions of the county wherein said practitioner shall attempt to practise, and shall furnish satisfactory evidence to such clerk that the provisions of this act have been complied with, and shall, in addition, take out a license for one year, and pay into the county treasury, for the use of such county, the sum of two hundred dollars therefor, whereupon it shall be the duty of such clerk to issue to such applicant a proper certificate of license, on payment of the fee of two dollars for his services: *Provided, however,*

That the announcement of name, title, and place of business by card, or announcement of name, title, and place of business in newspaper or other periodical, shall be sanctioned as legitimate, and is so approved by this act.

SECTION 6. Any person violating the provisions of this act shall be deemed guilty of a misdemeanor, and on conviction shall be sentenced to pay a fine not exceeding five hundred dollars, for the use of the county wherein such misdemeanor is committed, or imprisonment not exceeding one year, or both, at the discretion of the court; any person so convicted shall not be entitled to any fee for services rendered, and if a fee shall have been paid, the patient, or his or her heirs, may recover the same as debts of like amount are now recoverable by law.

APPROVED—The 12th day of April, A.D. 1875.

J. F. HARTRANFT.

GLEANINGS FROM OUR EXCHANGES.

A GENUINE CENTENARIAN.—Sir Duncan Gibb recently made a post-mortem examination on a woman who died at the well-authenticated age of 112 years. Her various organs were in a wonderfully healthy condition, scarcely any changes being observed, excepting that her heart was enlarged slightly, and there was great decrease in fatty tissue. Her death was said to have been caused by a "cold;" but, beyond slight congestion of the lungs, no disease of the respiratory apparatus was made out.

POISONING BY BICHROMATE OF POTASSIUM.—A photographer, in London, recently drank a quantity of a strong solution of bichromate of potassium, having mistaken the jug for another which contained ale. The physician called in found him very prostrate, sweating profusely, and complaining of severe abdominal pains. He was also slightly purged, the evacuations being of a greenish-yellow color. The pupils were dilated, and the pulse very weak and fluttering. Sulphate of zinc in water was administered two or three times, until vomiting and active purgation had been induced. Subsequently, olive-oil was given him. He remained very weak for some time, and the stomach could only tolerate the mildest food.—*British Medical Journal*.

APPLICATION OF COTTON-WOOL TO THE MEATUS AUDITORIUS.—Mr. G. F. Hodgson writes to the *British Medical Journal*, March 27, combating the statement recently made that cotton-wool is injurious to the ears.

It is true that if cotton-wool be pushed far into an ear whose cutaneous lining is already in a congested or irritable condition, it will, most likely, do more harm than good. The value of cotton-wool, however, when properly employed in cases of otorrhœa and perforated or lost membrana tympani, is beyond price. In England there are hundreds of persons who are daily introducing and wearing these little pledgets of cotton-wool pushed home against the remnants of their "drums," not only without the slightest inconvenience but with immense benefit. As a rule, these dossils are not introduced dry, but saturated with plain water, glycerin, oil, or other fluid, according to circumstances; and it is a good plan to remoisten them if they have been in any time.

COPPER IN THE LIVER.—M. Bourneville contributes (*Le Progrès Médical*, No. 32, 1874, *et seq.*) an account of certain observations made at the Salpêtrière concerning epilepsy. In one patient who had been treated by ammoniacal sulphate of copper, careful examination of the liver was made after death, with a view to ascertaining whether this salt is absorbed by the organ in question. From the analysis made, it would appear that

when ammoniacal sulphate of copper has been used in medicinal doses for some time, it may become stored away in the liver in considerable quantities. It follows from this that in medico-legal cases much reason should be exercised in drawing inferences from the presence of copper in the liver.

EXCESSIVE HEMORRHAGE FROM EXCISION OF THE TONSIL CONTROLLED BY ICE-PACKING OF THE THROAT.—Dr. Fauntleroy, of Staunton, Va., reports the following case in the *American Medical Weekly* for April 10. Having removed a very much enlarged tonsil by the usual process of excision with the tonsillotome, after fifteen or twenty minutes the wound commenced to bleed profusely. Solution of Monsel's salt and gargling with iced solution of common salt failed to check the hemorrhage, and Dr. F. finally had recourse to the ice-pack, applied behind the angle of the jaw and along the line of the cervical blood-vessels. This application was continued for more than an hour, the hemorrhage decreasing gradually during that time, and finally ceasing entirely.

INFLUENCE OF MATERNAL IMPRESSIONS ON THE FÆTUS.—F. Ormrod writes to the *Lancet*, March 13, an account of a woman who had her right hand trapped by the slamming of a door during the early period of utero-gestation. She was delivered in due time of a female child, normal in every respect excepting the fingers of the right hand, which were arrested in development. At the present time the child is over two years of age. The thumb and palm of the hand are quite natural; but the fingers measure only about half an inch in length, and are apparently without bones.

ACUTE GLOSSITIS IN SCARLATINA.—An instance of this extremely rare complication has lately been published by Dr. William Moore, of Dublin. It occurred in a young gentleman aged 18, and was the only example Dr. Moore had ever seen in this disease. He strongly advocates the treatment by iron and stimulants, when this complication takes place. A somewhat similar case has been described as occurring in the practice of Dr. Banks, but the complication is unusual.

TRICHINA.—Dr. Van Petri, of Rostock, has examined all the swine slaughtered in that town during the year 1874, for the purpose of ascertaining how many of these animals were infested by trichinæ. Out of 6731 thus examined, only two proved to contain these parasites.—*Virchow's Archiv*, February 15.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MAY 4, 1875, TO MAY 10, 1875, INCLUSIVE.

KEENEY, C. C., SURGEON.—During the absence of the Medical Director of the Department, to perform his duties. S. O. 40, Department of California, April 29, 1875.

BAILY, J. C., SURGEON.—Assigned to duty at the Post of Columbia, S. C. S. O. 59, Department of the South, May 6, 1875.

FRANTZ, J. H., SURGEON.—Relieved from duty at Columbia, S. C., and to comply with S. O. 73, c. s., A. G. O. S. O. 59, c. s., Department of the South.

GIBSON, J. R., ASSISTANT-SURGEON.—When relieved by Assistant-Surgeon De Witt, to comply with S. O. 73, c. s., A. G. O.

DE WITT, C., ASSISTANT-SURGEON.—Assigned to duty at Charleston, S. C. S. O. 59, c. s., Department of the South.

WEISEL, D., ASSISTANT-SURGEON.—Granted leave of absence for one month. S. O. 56, Department of the South, May 1, 1875.

FINLEY, J. A., ASSISTANT-SURGEON.—Assigned to duty at the Cantonment on the North Fork of Red River, Texas. S. O. 67, Department of the Missouri, May 5, 1875.

DE LOFFRE, A. A., ASSISTANT-SURGEON.—When relieved by Assistant-Surgeon Finley, assigned to duty at Fort Larned, Kansas. S. O. 67, c. s., Department of the Missouri.

MAUS, L. M., ASSISTANT-SURGEON.—Assigned to duty at Frankfort, Kentucky. S. O. 59, c. s., Department of the South.

PHILADELPHIA MEDICAL TIMES.

SATURDAY, MAY 22, 1875.

ADDRESS.

A LOST ART OF MEDICINE.

An Address delivered before the American Medical Association

BY S. D. GROSS, M.D.

WE here reproduce in full, with the exception of some preliminary opening matter, the address of Prof. Gross before the American Medical Association. After contrasting the present disuse of venesection with the universal employment of it in his boyhood, and asserting that bleeding is emphatically one of the lost arts, the venerable Professor continued as follows:

How this extraordinary change in sentiment and practice was brought about, by what influence, agency, authority, philosophy, logic, or mode of reasoning, is a matter worthy of brief inquiry. The causes, so far as they are patent to my mind, are mainly four: First, the influence or tyranny of authority, soon passing into more or less extensive fashion; secondly, the indiscriminate employment of the lancet in the days of what has been termed, not inappropriately, the Sangrado practice; thirdly, a more accurate knowledge of the nature and seat of diseases; and, lastly, the use of certain remedies unknown a third of a century ago, but now of general, if not universal, resort, in the treatment of inflammatory affections.

1. The influence of authority annually slays millions of human beings. Its pernicious effects upon human life, in its individual and collective relations, are felt in every direction; in the construction of our dwellings, in our habits and occupations, in our dress, in our social entertainments, in our amusements, in our food and drink, and in a thousand other ways. Of its malign influence in our profession examples daily fall under our observation, as the result of pernicious doctrines and practices. Superstition and fanaticism have kept the world in a state of intellectual bondage from the earliest records of society down to the present moment. The spiritualism of the present day has its counterpart in the witchcraft of three centuries ago, fortunately without the hangman's halter. Every age has its peculiar absurdities, characteristic of the minds of some of its people. Mesmerism deluded thousands of persons. The metallic tractors of Perkins enjoyed for a time a world-wide notoriety. Homœopathy is still at work in deluding the world. Clairvoyance has many devout adherents. Berkeley, in the middle of the last century, effected many wonderful cures with the aid of his tar-water. For upwards of one hundred years the lancet enjoyed unlimited sway. Everybody was bled. Surgeons, during the last dozen years, have had carbolic acid on the brain as a dressing in wounds and other injuries. Broussais, Cookeism, and the blue pill of Abernethy, each had a reign of at least a quarter of a century. For an equally long period the medical mind of Italy was agitated by the tartar-emic treatment of Rasori and his followers. Thompsonianism, or the lobelia and cayenne-pepper treatment, is not yet entirely extinct on this continent, although its days were numbered long ago. For nearly a third of a century the doctrine of a change of type in disease has tyrannized over the minds of medical men, and exerted a controlling influence upon their practice. Of all these delusions, the latter, often called Toddism, after Dr. Todd, its author, has exercised the most pervasive and baneful effects upon civilized society. Ensconcing itself

behind a false position, it has literally enslaved the medical world, entrapping alike the wise and the foolish, and sweeping over human life with a force equal to that of the fiercest and most destructive hurricane. Unlike the doctrine of sthenic and asthenic diseases of Dr. John Brown, who in the latter part of the last century enjoyed such a wide celebrity as a medical reformer, it assumes that all maladies are of a low type, imperatively demanding the use of stimulants for their successful management. It countenances no half-way measures. The patient must be upheld by stimulants or he must die. Now and then, perhaps, a few leeches may be tolerated, but only in very exceptional cases, where there is not too much depression of the vital powers. Who and what Dr. Todd, the author of this system of medicine, was, it would be needless to inquire. Everybody knows that he was one of the ablest writers and clinical teachers whom this century has produced; but that he was a profound thinker, I doubt; and it is well to bear in mind that the class of patients at King's College Hospital, London, of which he had charge, were persons in the lower walks of life, broken down by overwork, privation, and various forms of intemperance, and therefore unable to bear depletory remedies. Such patients as Dr. Todd had are to be found in the wards of every eleemosynary institution in Europe and in this country. It was from a study of this class of cases that this famous man, in an evil hour, deduced the absurd doctrine of a change of type in disease. I say absurd, for if there ever was anything absurd this doctrine most assuredly deserves that name. Who, that has any knowledge of the human constitution as it is daily met with in our intercourse with our fellow-citizens, in the various pursuits of life, will lend credence to such an idea,—I had almost said to such a slander? I assert, without the fear of successful contradiction, that man's power of endurance in health and disease is not one particle less than it was fifty years ago, when depletory measures of every form were the order of the day; when, in fact, it would have been deemed derogatory to a physician's character to let a patient die without the aid of such remedies. The exploits performed during our late terrible war alone are sufficient to settle this question. Never, since man battled with man for national supremacy, were there so many rapid, laborious, and brilliant marches executed in so short a time as there were on both sides of the line. The exploits of the soldiers of Alexander, Hannibal, Cæsar, and Bonaparte fade into comparative insignificance by the side of those of some of our generals. Our laborers, farmers, miners, hewers of wood, carriers of water, mechanics, artisans, and professional men, evince no evidence of decline in muscular power or mental endurance. Our sailors are as hardy a race of men as they were in the days of Sir Francis Drake or Captain Cook.

If we look at the habits and modes of life of the people of the present day, it will be found, if I do not greatly err, that they do not differ, in any essential manner, from those of a third of a century ago. The different classes of men and women, in city and in country, live very much as they did in my boyhood, using the same kind of food and drink, pursuing similar occupations and amusements, and exercising as much control over their appetites and passions generally as their fathers and mothers. If there are any differences in any of these particulars, they are certainly not well marked, nor so radical in their character as to diminish, in any material degree, the power of endurance of our people in health and disease. On the other hand, owing to the more extensive cultivation of our soil, the destruction of our forests, the draining of our

marshes, and the greater attention paid to the study of hygiene, our people, especially those in the rural districts, are much more exempt from the diseases caused by the noxious exhalations from the earth's surface, so prevalent in newly-settled countries, and so pernicious in their effects upon the constitution, than they were in the early days of my white- and bald-headed contemporaries.

Do not men during accidents and surgical operations, and women during parturition, often lose enormous quantities of blood, and yet frequently make excellent recoveries? In epistaxis, hæmoptysis, and hæmatemesis, this fluid is often largely poured out, and yet it is seldom that we hear of a person dying from the effects of its loss.

In the face of such facts as these, and a hundred others that might be adduced if time permitted, the doctrine of a change of type in disease must fall to the ground as utterly untenable.

The influence of fashion is not limited to our profession. We all recollect how the crinoline of the French Empress, invented to conceal a condition of which most ladies are so proud, enslaved the female mind, until every woman, married and single, considered it as an indispensable article of dress. A sofa, however spacious, was hardly long enough for a woman thus arrayed to sit upon. How the fashion has changed within the last six or eight years is familiar to everybody. Now the dress is so narrow as to show the outline of the person, and compel the greatest care in progressing lest the fair wearer should trip and tear her garments. Even diseases occasionally become fashionable. When it became known that Louis XIV. was laboring under anal fistula, the disgusting malady became at once the fashionable ailment of his debauched court. The use of enemata was cultivated as one of the fine arts in France in the time of Molière, who lashed the faculty without mercy for its follies and extravagances.

Second.—The indiscriminate employment of the lancet in former days did much to bring blood-letting into discredit, not only with the better thinking class of physicians, but the public at large. "We cure the sick," says Gui Patin, a professor in the Royal College of France, "when over eighty years old, by blood-letting, and also infants of not more than two or three months, with as much success and as little inconvenience." Rush, the great champion of this operation on this side of the Atlantic, bled indiscriminately and remorselessly at all periods of life, the young, the middle-aged, and the old; in all kinds of diseases, in the eruptive fevers, in fever and ague, in puerperal fever, in inflammations, in injuries, in hemorrhages, and even in anæmia, often taking immense quantities of blood, and repeating the operation six, eight, or even a dozen times in the same patient. In short, he and his followers used to bleed in every possible disorder until, in many cases, no more blood would flow, because there was none left. That such a practice would at length work out its own destruction is what might reasonably have been expected. It rang its own knell.

Third.—That we are much better acquainted with the nature and treatment of disease than our fathers were is a fact so universally accepted as to require no argument in its support. Our progress in this respect, during the last forty years, has simply been marvellous; and to nothing are we so much indebted for these improvements as to the study of pathological anatomy and histology, and the astounding developments of chemical science.

Fourth.—That the treatment of disease has been greatly simplified within the period above specified is familiar to every member of the profession. Homœopathy, by the absurdities of its doctrines and primi-

tive practices, long ago demonstrated to the world that most of its cures are effected spontaneously, through nature's restorative powers alone, while the patient's mind is medicated with the decillionth part of a drop or a grain of medicine; and in comparatively recent years two eminent medical philosophers, Professor Bigelow, of Boston, and Sir John Forbes, of London, showed us, by a series of admirably-conducted observations, that certain diseases, as smallpox, scarlatina, measles, typhus and typhoid fevers, are self-limited in character, and therefore not to be materially if at all abridged in their course by any plan or means of medication whatever. A third of a century ago the only so-called depressants, aside from the use of the lancet, were tartar emetic, calomel, and digitalis, the latter of doubtful efficacy in any case, and the first often exhibited without due discrimination. Of aconite and veratrum viride, now so universally employed as antiphlogistic agents, we were totally ignorant. These two medicines, as I shall endeavor to prove by-and-by, although frequently of immense service in the treatment of inflammatory affections, are far, far inferior to blood-letting.

Believing that these are the principal, if not the only, reasons which have led to the abandonment of blood-letting as a therapeutic agent, I propose now to speak of the operation itself, and to point out, first, the classes of diseases to which it is more especially applicable; secondly, the period at which it should be performed to yield the greatest amount of good; and, lastly, its mode of action.

Blood may be abstracted in different ways, as, first, by venesection; secondly, by leeches and cups; thirdly, by incision, scarification, or puncture; and fourthly, by arteriotomy. The latter operation is so difficult of performance that few practitioners are willing to attempt it. There are cases, as in violent inflammation of the brain, eye, and ear, in which it is supposed to exercise a peculiarly beneficial influence; but, generally speaking, it is quite certain that venesection, if properly executed, answers every purpose, even in the affections here specified. Similar remarks are applicable to bleeding at the jugular vein, also usually a difficult and, sometimes, even a dangerous operation.

The diseases to which blood-letting is more particularly applicable are the different inflammations, acute and chronic; general bleeding being best adapted to the former, and local to the latter. Hippocrates and his immediate followers bled largely in pneumonia and pleurisy, and Sydenham, Rush, Louis, Drake, and many others often took immense quantities of blood in the treatment of these maladies. In acute inflammation of the eye, in robust subjects, bleeding is often indispensably necessary to save the affected organ. Who would hesitate to draw blood largely, under similar circumstances, in acute inflammation of the brain and its envelope, in acute pericarditis or endocarditis, in hepatitis, splenitis, gastritis, enteritis, peritonitis, cystitis, metritis, or orchitis? Stricture of the urethra would be much less frequent if young men laboring under severe gonorrhœa were freely bled at the beginning of the attack. In traumatic affections of the joints, untended with loss of blood or severe shock, the abstraction of blood would often prevent ankylosis, so common under the present system of treatment. The spasm which is so often present in recent fractures, especially in those of the leg and thigh, is more readily controlled by venesection, followed by a hypodermic injection of morphia, than by any other agent I have ever tried.

In chronic inflammation, blood-letting is often an indispensable remedy. Even the most ultra advocate of the stimulant method of treatment will hesitate to employ it when destructive action is gradually but surely undermining structure and function. The abstraction of five, eight, or even ten ounces of blood in chronic

pneumonia and pleurisy, especially when associated with severe pain and obstructed respiration, often acts like a charm, relieving suffering and promoting the beneficial action of other measures. In chronic ophthalmia a few leeches applied to the fore part of the temple, on a line with the commissure of the lids, frequently produce the happiest result. But I will not consume your time by an enumeration of the different cases of chronic inflammation in which blood-letting might be advantageous. What I have said respecting the lungs, pleuræ, and eye is equally applicable to other structures, and needs no further elucidation here.

It requires no labored argument to show that general bleeding can be successfully practised only at the beginning of an acute disease, or during its earlier and graver stages. Performed at a later period, when the morbid action is fully established and the affected tissues are inundated with inflammatory deposits, it cannot fail to do harm by robbing the system of the strength so much needed to carry on its vital processes. A copious bleeding at the outset of a violent inflammatory disease is gold; but at its height, lead; or, to express myself more clearly, life in the one case, death in the other.

Secondly.—To draw blood to the greatest possible advantage, the quantity should be measured, not by ounces, but by the impression it makes upon the system, as denoted by the pallor of the countenance, the reduction of the heart's action, the softened state of the pulse and skin, the abatement of pain and of other symptoms, as headache, thirst, and restlessness, so universally present in all severe inflammatory attacks. To insure this result in the most speedy and decided manner, the blood should be drawn from a large orifice in a large vein at the rate of two and a half to three ounces in the minute, while the patient is in the erect or semi-erect posture. If the body be recumbent during the operation, a much larger quantity of blood will be required to be drawn to produce the desired effect than when the reverse is the case. While, therefore, the bleeding should be spoliative, care should be taken not to waste the fluid unnecessarily.

To prevent undue reaction after the operation, the bleeding should not be carried to complete syncope, but merely to an approach to this condition, the effect of the operation being carefully watched by a reference to the countenance and the pulse, lest it should exceed the proper limits, and thus do harm instead of good. Violent reaction, however, in any case, after the abstraction of blood, may generally be effectually prevented by a full dose of some diaphoretic anodyne, as ten grains of Dover's powder with one-fourth of a grain of morphia, given immediately after the operation.

Respecting the repetition of the operation, every case must, so to speak, make its own rules. If, after a very copious bleeding, the symptoms rapidly reappear in all or nearly all their former intensity, the operation should at once be repeated, either by reopening the original orifice or by selecting another vein. In urgent cases, as in violent pneumonia, pleurisy, peritonitis, cerebritis, or endocarditis, the operation may often be repeated several times in rapid succession. Under such circumstances, the practitioner must, like a wary general, make forced marches, and follow up his successes, not waiting until the enemy has intrenched himself behind his works, but striking heavy blows while he has the opportunity.

But I shall be told that such heroic treatment must inevitably induce serious debility. I grant it will; but in turn I ask, will the disease, if neglected or permitted to progress, not also cause debility,—debility, perhaps, of the very worst kind,—debility from over-action of the heart, imperfect supply of nerve-fluid, deranged circulation, impaired function of vital organs, and, above all, from disordered structure from inflammatory deposits?

The enlightened practitioner bleeds to save tissue, and to prevent the morbid action from running riot. He repairs strength, when the time for it arrives, by making blood with nutritious food and drink, and thus speedily sets the machinery of life again in motion. The timid, hesitating practitioner, the opponent of bleeding, on the contrary, although he may employ the same restoratives, uses them inopportunistically, and thus allows the debility caused by his treatment to linger for an indefinite time, provided the patient is so fortunate as to survive the first onslaught of his disease.

Before I proceed to speak of local bleeding, let us briefly inquire into the mode of action of venesection, or, in other words, how the removal of blood from the system affords relief in inflammatory affections. This question can be easily answered. In the first place, the abstraction acts spoliatively, diminishing, as the name implies, the quantity of blood, both in the part and system. Secondly, it weakens the power of the heart, and thereby prevents it from sending the blood with the same force and velocity into the suffering structures. Thirdly, it unlocks all the emunctories, and thus promotes secretion. Fourthly, it discharges the vessels at the seat of the disease, restores the circulation, and places the absorbent vessels in a better condition for the removal of effused matter. And, last, but not least, it favors the action of other remedies, as purgatives, diaphoretics, diuretics, and anodynes.

But it will be said that all these effects may and can readily be induced by the agency of other remedies, as aconite, veratrum viride, digitalis, mercury, and tartar emetic, and that, too, at much less cost to the system. That these articles are powerful depressants, lowering the heart's action and promoting secretion, no one at all acquainted with their virtues will question; but I deny that they exercise the same beneficial impression upon the vessels at the seat of the inflammation. When blood is drawn freely from a large vein at the bend of the arm, from a large orifice, to an approach to syncope, the vessels at the seat of the morbid action are unloaded, often to such an extent that the affected structures do not exhibit any marked difference in color from those in their immediate vicinity. Thus, for example, in violent conjunctivitis the mucous membrane, the seat of the disease, always, under such circumstances, presents a perfectly blanched appearance, however red and engorged it may have been the moment before. Now, what occurs in the eye, in such a case, may reasonably be supposed to take place in any other part of the body when a patient is bled to a similar extent. In pleurisy, one of the immediate effects of the copious abstraction of blood is a mitigation of the torturing pain which forms so prominent a symptom in this disease, due, evidently, to the diminished calibre of the vessels in the pleura, previously in a state of complete repletion. Has any one ever witnessed such an effect from the exhibition of aconite, digitalis, veratrum viride, or tartar emetic? Never. No matter how these articles may be administered, whether singly or variously combined, they are simply depressants, not depressants and evacuants, as the abstraction of blood from a vein or an artery; there is no blanching of tissue from their use, no unloading of distended and crippled vessels,—indeed, no direct appreciable effect of any kind.

The more recent researches in pathological histology furnish a hint not easily to be mistaken as to the most salient treatment of inflammation in its earlier stages. The leading indication is to restore the paralyzed capillaries to their normal tonicity, so as to prevent structural changes in their walls, and facilitate the outward passage of the white globules with which they are choked. It is now well known that in every inflamed area there is marked hyperæmic distention of the blood-vessels, which are often crowded to their utmost capacity

with leucocytes, which emigrate through the vascular walls, and, in conjunction with the effused blood-liquor, constitute the most important elements in inflammatory deposits. Hence the object of treatment should be to restore the capillaries to their normal calibre through the artificial induction of contraction of their walls,—an effect which can be brought about, as is daily witnessed in many of the external inflammations, by cold applications, which, as is well ascertained, produce reflex contraction of the vessels. In inflammation of the more deeply-seated organs and tissues, however, this object can only be attained by spoliative bleeding, whereby the affected capillaries are relieved of their contents. In this way only can their tonicity be restored, the further effusion or migration of cell-elements restrained, and the absorption of existing deposits favored.

Another effect of bleeding, not to be overlooked in this discussion, is the diminution which it causes in the quantity of fibrine and white globules, so remarkably augmented in inflammatory affections. This change, of which I have witnessed many examples, was beautifully illustrated in the case of a young man, nineteen years of age, whom I attended along with the late Dr. Charles Woodward, of Cincinnati, on account of a severe attack of pleurisy. Blood was drawn on three consecutive days, the first bleeding being performed about thirty-six hours from the commencement of the attack. The fluid, amounting to nearly a quart, was not only greatly buffed, but cupped on both sides of the crassamentum, as is shown in the specimen which is still in my possession. At the second operation the fluid was buffed, but not cupped; and at the third it was merely a little sized, all pain and active inflammation having by this time disappeared. If such effects follow the use of the articles above mentioned, I am uninformed of the fact.

In leeching and cupping, blood may be taken directly from the affected structures, or indirectly, as when they are practised at a distance from the seat of the inflammation; in the latter case the effect, if carried to a great extent, is similar to that produced in venesection, but generally much more tardy, and, therefore, in the main, not so efficacious. When the tissues are divided, as in incisions, scarification, or puncture, the vessels are directly drained of their contents, an operation often followed by great, if not permanent, relief. Illustrations of the efficacy of this mode of depletion are daily witnessed in tonsillitis, in erysipelas, ulcers of the extremities, inflammation of the uterus, and in impending mortification, not to mention other affections.

I have said that general bleeding can be successfully practised only at the beginning of an inflammatory attack, a fact which, I repeat it, is not to be lost sight of in weighing the propriety of such a procedure. Let it be borne in mind also that bleeding is not to be practised indiscriminately, but judiciously, and with proper regard to the condition of the system. Our fathers grievously erred, because they bled in every stage of disease, and in all states of the system, the plethoric and the anæmic, the strong and the weak. Of course there were exceptions, but as a rule this was the practice; the harm, hence, as a natural consequence of the abuse, the abandonment of the treatment. It is within the recollection of all the older members of this Association when the practice of medicine in this country and in Great Britain was limited to the lancet, calomel, digitalis, opiates, and tartar emetic, with gruel and chicken-broth as the chief diet during sickness. I well remember the time when the use of cold water was interdicted as highly improper, especially in the treatment of the so-called eruptive fevers, and when ventilation of a sick man's chamber was considered as fraught with danger. Bleeding will again come into fashion; history constantly repeats itself, and knowledge runs in a circle.

No sensible man can fail to read the signs of the times; but it will not be indiscriminate bleeding, but bleeding performed for a reason, early, and, if need be, freely, to save tissue and promote resolution; in the robust and plethoric, in the young and middle-aged, not in the weak, the anæmic, the intemperate, the broken-down, and the decrepit. Practitioners during the last third of a century have labored under a delusion and a dream, from which they are gradually emerging to a sense of their duty; and, although I am not a prophet or the son of a prophet, I venture to predict that the day is near at hand, if indeed it has not already arrived, when this important element of treatment, so long and so shamefully neglected, will again become a recognized therapeutic agent, and will thus be instrumental in saving many lives, many an eye, many a lung, many a joint, and many a limb.

But bleeding should not be restricted to the treatment of inflammatory diseases. There are other affections in which it may often be practised with the greatest benefit. In puerperal convulsions, attended with a plethoric condition of the system, copious venesection, promptly followed by the administration of a full anodyne, either alone or in union with chloral and bromide of ammonium, and the application of leeches to the temples and cold to the head, is the sheet-anchor of our hopes, a positive *sine qua non* to success. An experienced and learned member of this Association, Dr. J. Fordyce Barker, recently called attention to this subject in a paper characterized by strong sense and great practical acumen, worthy of his high position as an accomplished gynaecologist. I believe, indeed, that the practice thus set down is the one now generally, if not universally, adopted in the treatment of this dangerous disease, as it was in the time of Dewees and his more enlightened contemporaries. In certain forms of apoplexy the judicious employment of the lancet cannot be too strongly insisted upon, especially in comparatively young and vigorous subjects. Blood in this disease is often taken with leeches when it ought to be taken with the lancet. In asthma, bleeding is frequently of inestimable value, in relieving engorgement and spasm of the lungs, the causes of the terrible dyspnoea so often present in the more aggravated forms of the disease. I recall to mind the case of a lady who was the subject of asthma from the age of fourteen up to that of eighty-six, when she died of pneumonia, whom I repeatedly bled with the greatest advantage in attacks of this kind, which nothing else could relieve. In another case, that of a tall, slender gentleman of this city, nearly eighty years of age, in which a severe attack of asthma was complicated with great congestion and slight inflammation of the lungs, the abstraction of less than ten ounces of blood by the lancet led to a speedy convalescence and a complete cure. I verily believe that if this gentleman had not been bled he would have died. In certain forms of phthisis, venesection, judiciously employed, is frequently productive of great benefit. I allude more particularly to the chronic variety of the disease, kept for years in abeyance by great care and a properly regulated regimen. I remember the case of the late Mr. Benjamin Drake, of Cincinnati, a brother of the great professor, who labored for many years under disease of the lungs, associated with tubercular deposits, the more urgent symptoms of which were always promptly relieved by the loss of eight to sixteen ounces of blood by venesection. I have always felt satisfied that his life was materially prolonged by this treatment. Dr. Rush was in the habit, as Sydenham had been before him, of bleeding in every case of phthisis attended with a hard pulse, or a pulse rendered weak by the laborious transmission of blood through the lungs. In one of his cases he bled eighteen times in two weeks, and in another, fifteen times in six weeks, with the happiest

effect. I do not cite these instances as examples for our imitation, but simply to show that a system borne down by disease may react favorably under what to us of the present day appears as a most heroic measure.

Forty years ago it was customary in protracted labor, dependent upon rigidity of the uterus and the perineum, to bleed in order to relax the parts and expedite the expulsion of the child. Dewees, in such cases, often took large quantities of blood, especially in young, robust, primiparous women, and occasionally even repeated the bleeding. I well remember that this was the general practice for a number of years after I entered the profession. Why it has fallen into desuetude it would be difficult to tell. The abstraction of blood under such circumstances was always followed by the exhibition of a large anodyne, under the influence of which the labor usually progressed rapidly to a favorable issue, without subjecting the poor woman to undue torture, the danger of lacerating the perineum, or the necessity of applying the forceps, the use of which is now so common among all classes of accoucheurs.

The plethoric condition of the system so frequently met with in young, robust, pregnant women is generally promptly relieved by the abstraction of twelve to fifteen ounces of blood, and certainly there is no more rational remedy in such circumstances, especially when the redundancy of blood is accompanied by dizziness, vertigo, or headache. Thirty years ago there were few women that were not bled once or twice during uterogestation on account of the symptoms, and I do not know that I ever heard of one that was injured by the practice.

Certain forms of hysteria and epileptic convulsions, dependent upon congestion of the nervous centres and a redundancy of blood in the system, are generally materially benefited by venesection. The relief in the former affection is often prompt and permanent, as I can testify from personal experience.

In the convulsions of infants blood-letting is frequently of signal service. In that form of the disease which follows upon the more severe attacks of cholera, so rife in our hot summer months, and which are manifestly due to over-excitement of the brain, as is shown by the excessive heat of the head, the flushed condition of the countenance, the suffused eye, the intense thirst, the incessant restlessness, the intolerance of light and noise, and the twitching of the muscles, the abstraction of two to two ounces and a half of blood from the arm, in a child from one to two years of age, not only, in many cases, promptly arrests the vomiting and other distressing symptoms, but protects the brain from more serious mischief, and thus places the system in a condition for speedy convalescence.

In what is called hay-fever, a good bleeding sometimes affords immediate alleviation of all the disagreeable suffering incident to that complaint, as dyspnoea, violent sneezing, nasal catarrh, tightness in the frontal sinuses, headache, and horripilations, or chilly sensations along the course of the spine. I recollect one case which came under my observation many years ago, in a clerical gentleman, thirty-three years of age, who, on being largely bled one Sunday soon after the close of his religious services, was completely cured for that season; and, although the malady recurred during several consecutive summers afterwards, the attacks were always comparatively light.

Cases have been related of great benefit afforded by bleeding in uræmic coma, attended with unconsciousness, dilated and fixed pupils, convulsions, a highly albuminous condition of the urine, and excessive prostration of the system. The blood at first issued feebly, but gradually the stream increased in volume, the blood assumed a brighter hue, the pulse rose, the convulsions ceased, consciousness returned, and the patient finally

made an excellent recovery. Several such examples will be found recorded in the *London Medical Times and Gazette* for September, 1874, by Dr. Benjamin W. Richardson, in an article on "Blood-letting as a Point of Scientific Practice," and are worthy of special study.

This spring twelve months ago I was requested to visit a lady, a stout, muscular person, in robust health, upwards of forty years of age, who for several years past had suffered much from attacks of headache, attended with dizziness, and occasionally, also, with vertigo. She had tried various remedies without benefit. I suggested bleeding, to which she at once assented, and I drew fully three half-pints of blood, with immediate and permanent relief.

Surgeons the world over draw blood after severe reaction in concussion of the brain, to prevent inflammation of that organ and of its membranes. The more plethoric the patient the greater the necessity for such interference; but the operation should by no means be restricted to this condition, as it is often of great value, if timeously performed, in the comparatively anæmic subjects. It was a case of concussion of the brain that gave rise to the never-to-be-forgotten conversation between John Hunter and his pupil, Dr. Physick, at the time resident physician at St. George's Hospital, London. A man laboring under concussion of the brain from a fall from a scaffold was brought into the surgical ward in a state of utter unconsciousness. "What shall I do?" said the pupil to his master. "Shall I bleed him?" "Bleed him? Bleed him, sir? No, sir! You would kill him outright. Wait, sir, until he reacts, and then bleed him,—bleed him to death, sir." [Dr. Charles D. Meigs, in *Pennsylvania Hospital Reports*, vol. i. p. 27, 1868.] In compression of the brain from fracture, with depression of bone and compression from extravasation of blood, the abstraction of blood by the lancet and leeches is frequently resorted to for the purpose of securing cerebral accommodation, and the practice, as is well known, is often followed by the most gratifying results.

We all have, at some period or other of our lives, experienced the torturing, racking pains in the back and limbs, so common in bilious, remittent, and intermittent fevers, as if the body was about to be broken in two, causing us to turn and toss about almost incessantly in search of ease; the head generally at the same time terribly distressed, the skin hot and dry, the thirst intense, and the heart in wild, tumultuous motion. Who that has ever been freely bled in such a condition of the system does not remember with grateful feelings the prompt alleviation afforded by the operation? The application of a dozen wet cups to the aching back has often speedily transported the poor patient, as it were, from torment into elysium. In gout and rheumatism the abstraction of blood is frequently of immense benefit, if not as a direct curative agent, as a means of relieving pain and paving the way for the more successful action of other remedies. The passage of renal and biliary calculi is often greatly expedited, and the suffering caused by it much alleviated by a copious bleeding, especially in stout, plethoric subjects.

But I must stop, for my remarks have already been extended far beyond my original design, which was simply to point out a few of the more prominent diseases in which, in my humble opinion, this much-neglected but most valuable therapeutic agent may be advantageously employed.

The fate of blood-letting, Mr. Chairman, teaches us an important lesson, not at all calculated to elevate our pride as men intrusted with the preservation of the health and lives of our fellow-beings. It shows what little faith there is to be placed in human judgment, and how sadly we are influenced by authority and fashion in a matter pertaining to the dearest interests of society.

If I wished to be satirical, I should say that there are in our profession, as there are, indeed, in every other, two distinct classes of men,—the thinking and the non-thinking. The former, whose number is exceedingly limited, accept every novelty, or great and sudden change, with suspicion, wisely concluding that the one ought not to be adopted until it has been fairly tested by well-conducted observation and experiment, and that the other should not be rejected without sufficient cause. The non-thinking man, on the contrary, eagerly lays hold of every novelty, and seldom stops to seek a reason for his new faith. He adopts it simply because his neighbor adopts it. Especially is this the case when the novelty, whatever it may be, has a distinguished parentage, as when it has received the sanction of a great name, or, perchance, if it had a transatlantic origin. Jones, Robinson, or Brown, in Europe, is always a great man, far greater than his namesake on this side of the water. This non-thinking man confounds progress with improvement. He does not weigh the pros and cons of a question; he takes a shorter route; sees things in a distorted light; assumes for granted what he cannot comprehend, and jumps at conclusions. As the sheep follows the wether, so he follows his master, looks through his spectacles, believes in his infallibility, and swears by his authority. The more the assertion borders on the marvellous, the more greedily does he gulp it, so much easier is it to assume the truth of a proposition or statement than to prove it by sound logical argument and inductive reasoning. I think I am not guilty of exaggeration in what I say. It really seems to me as if we were bereft of our senses. No sooner is a new remedy, an operation, or a method of treatment introduced to notice, than it is puffed into gigantic proportions and endowed with virtues as foreign to it as any other folly under heaven. Certain it is, there never was any greater need for deliberation and reflection than there is at the present time; greater need of asking ourselves, "Watchman, what of the night?"

ORIGINAL COMMUNICATIONS.

CARIES OF MASTOID CELLS—REMOVAL OF SEQUESTRUM—FACIAL PARALYSIS AND RECOVERY.

BY CHARLES HENRY BURNETT, M.D.,

Aural Surgeon to the Presbyterian Hospital in Philadelphia.

THIS case came under my care last August (1874), through the kindness of my friend Dr. A. Douglass Hall.

The patient, a lad of 14 years, stated that he had had a neglected aural disease ever since childhood. Some weeks previously he had been attacked by severe pain in the left ear, after bathing in the sea, at Cape May, where he was employed. He then came to Philadelphia to obtain relief from the terrific pain in the ear, and applied to Dr. Hall, who made a deep incision over the mastoid process, giving vent to a large amount of exceedingly offensive pus, and relieving the suffering of the patient greatly. The next day Dr. Hall sent the boy to me. I found the lad very weak, with a pulse over 100, forehead bathed with clammy perspiration, anorexia, less pain since the mastoid incision, with considerable vertigo, and offensive purulent discharge from the ear and the incision over the mastoid process. I found that a probe entered the mastoid process

point-blank, three-fourths of an inch, coming in contact with dead bone. There was also a sinus running from the external auditory meatus, upwards and backwards, to dead bone in the mastoid cavity. The patient stated that about a year previous to this time a piece of dead bone had worked its way from the auditory meatus, after an attack of pain in the ear. A probe passed through the sinus in the auditory canal, and another passed through the sinus behind the auricle, could be made to touch each other in the mastoid cavity, and dead bone was felt everywhere in their path. The silver probe passing into the sinus running from the auditory meatus became instantly blackened, and from this sinus crumbs of black and offensive bone were constantly discharged for several days. At the point in the auditory meatus where the probe entered there was a large bunch of granulations, which was finally removed by a wire-snare. I could not detect any sequestrum at that time. I placed the boy in the Presbyterian Hospital, and gave him milk-punch and tincture of chloride of iron thrice daily for several weeks, during which period the pain became very much less in the ear; that which he still experienced was above, and running forward from the auricle. The vertigo disappeared, and the patient was able to take muscular exercise; the ear became less tender, and permitted all necessary manipulation, but the patient could not lie on the ear on a bed. Under this treatment the discharge grew less, and on the 24th of September I extracted, through the opening in the mastoid process, a spongy sequestrum one-half inch square, and then, placing the broad, blunt nozzle of a syringe in the opening, I gently injected a stream of warm water, which washed out a copious amount of large cheesy-looking masses through the external auditory meatus, and some portions of the mass, passing through the Eustachian tube, escaped by the mouth. The masses were composed of large acicular crystals of cholesterine and fatty epithelial debris, and strongly reminded one of the matter found in cholesteatoma of the ear, as described by Lucae, of Berlin (*Archiv für Ohrenheilk.*, Bd. i. No. 1). The removal of the sequestrum and the subsequent syringing, with its fruitful results, gave still further relief to the patient; all pain disappeared, and he could now lie with his ear downward in bed.

The sinus behind the auricle closed in four days after the removal of the sequestrum, and in a week from that time the discharge from the ear had almost ceased, and the odor of diseased bone, which had pervaded the patient, had disappeared; but I could still feel loose crumbs of dead bone lying in the sinus leading from the auditory meatus to the mastoid cells. Therefore, I widened the sinus with my knife, cutting from the meatus towards the mastoid process, and inserted a tent in the widened sinus. The tent was reinserted; for five days crumbling bone came away, the odor and discharge lessened, and the sinus in the meatus closed October 17, under instillations of a solution of sulphate of copper (3 gr. to f3j). The patient had become by this time quite strong under the constant use of tincture of chloride of iron, and, occasionally, alcoholic stimulants.

During the night of the 19th of October, four weeks after the removal of the mastoid sequestrum, the patient experienced some pain in the ear, but not enough to keep him awake. On the morning of the 20th, he found that "he could not whistle, and that the tears ran over his left cheek constantly." Facial paralysis became fully established on the left side by the 21st; so much so that food lodged between the cheek and teeth on the affected side. There was no continuance of pain, and the patient expressed himself as feeling very well. He took, without my consent, a situation offered to him, and went to work at this time, the paralysis disappearing in two weeks, as I learned subsequently, for I did not hear from him until a few weeks ago, when he visited me and I found him entirely free from paralysis and all aural discharge. He had continued, on his own responsibility, to take the tincture of the chloride of iron until the paralysis had disappeared.

Facial paralysis is not of frequent occurrence in necrosis of the mastoid process, and if it occur it is likely to be permanent. Its permanence is due to the erosion of the Fallopian canal, and an organic lesion of the facial nerve. Its occurrence and subsequent disappearance in this case is of interest and worthy of consideration. It can be explained, I think, as follows:

1. It is well known that the facial nerve will resist the chronic inflammation attacking the petrous bone, long after the Fallopian canal is destroyed. Gruber has reported a case, with an engraving, in which the facial nerve was exposed for two-thirds of its length in the tympanum, by necrosis of the Fallopian canal (Lehrbuch, p. 541), and yet no paralysis ever occurred.

2. It is therefore probable that, the facial nerve becoming unduly exposed, in the case I have described, by caries of the Fallopian tube, a slight acute inflammation in the middle ear furnished pressure sufficient to produce the functional paralysis. The disappearance of the paralysis was of course due to the absorption of the products of the acute inflammation, from which we may learn that, alarming as paralysis of the facial nerve is in *necrosis of the mastoid cells*, we are not obliged, when it occurs, to give an unfavorable prognosis, for we may have, as in this case, simply a temporary paralysis, due to pressure from an effusion of fluids, which can soon become absorbed and permit the nerve to resume its function.

TRANSLATIONS.

PRÆPUTIAL CALCULI.—Dr. F. W. Zahn communicates the following case to *Virchow's Archiv*, February 15, 1875:

The patient, a peasant 52 years of age, was found on examination to be suffering from cystitis, and, in addition, congenital phimosis. The præputial sac was stuffed with stony concretions of various sizes, which rendered urination a matter of some difficulty.

The patient had formerly made use of a catheter, and more recently of a knitting-needle, to press the stones back and thus allow of urination. Quite lately one or

more of the concretions had become dislodged, thus allowing a somewhat freer stream. As the cystitis seemed dependent upon the difficulty of urination, the operation for phimosis was suggested, which the patient refused. He was then put upon quinine, which relieved many of his symptoms, chill, etc., connected with the bladder-trouble.

Six months later, the patient came again under observation. The cystitis had continued, and he was weaker. Two more stones had been passed. An incision was now made, and the concretions removed. The largest of these, rough and convex on its surface and resting on the glans, caused a flattening of the glans, or rather an hour-glass contraction. The urethra was much narrowed to a point about three centimetres from its opening. This narrowing having been enlarged by a tent, the rest of the urethra was found of normal size.

Soon after this operation the patient began to show signs of renal disease, and finally died with symptoms of uræmic poisoning. Unfortunately, no post-mortem examination was allowed. The calculi, fourteen in number, weighed in all 28.5 grammes. The largest was egg-shaped, 29 millimetres long, 26 millimetres broad, and 22 millimetres thick, and had a volume of 9 cubic centimetres. This was the one referred to above as pressing upon the glans. The other concretions varied in size down to that of a peach-kernel, and were of various shapes and appearances. Section showed a central roundish nucleus, sometimes distinguished from the outer layers by being of a reddish color, in other cases by its softer consistency, but always homogeneous. Outside of this the accretion was arranged in concentric layers. The nuclei contained much horny epithelium, which was only sparingly found in the outer layers. After a somewhat minute discussion of the origin of these concretions in general, Dr. Zahn states it as his belief that they are formed around the "epithelial pearls" which are found in the smegma præputii of newly-born children. X.

CIRRHOSIS OF THE LIVER IN YOUNG CHILDREN.—Dr. Cazalis reports (*Le Progrès Médical*, No. 12, 1875) two cases of cirrhosis of the liver occurring in children seven and nine years of age, respectively. The first child had suffered much from cold, hunger, and privation during the siege of Paris. She presented, on admission to the hospital, moderate œdema of the lower members, abdomen distended with ascites, the superficial veins distended, not painful on pressure; face not swollen, but emaciated. Sonorous râles could be heard in the lungs. The urine contained albumen. About a week later an acute attack supervened, accompanied by very severe abdominal pains, like those of peritonitis, and intense dyspnœa, pulse 130.

During the next few days the dyspnœa diminished, but the ascites increased. Puncture of the abdominal cavity was followed by relief. No more fluid formed there; but the lungs became œdematous, and diarrhœa, erysipelas, and gangrene of the vulva supervened, followed by death. Post-mortem examination showed pleuritic effusion, moderate œdema of the lung with atelectasis of the lower border. The liver was very small, presented plaques of perihepatitis, was mammillated on the surface. The hepatic tissue was hard and resistant. The capsule of Glisson was enormously developed; the parenchymatous substance was circumscribed by fibrous tissue, hard, and of a uniform dark-brown color. The branches of the portal vein were surrounded by an abundant mass of fibrous tissue. The peritoneum was covered with false membrane.

The second case was, in the main, similar to the first. The child had lived in a damp ground-floor apartment, and in a miserable way. The symptoms were very similar to those of the first case, and the autopsy

showed, as in that instance, extreme atrophy of the liver, indications of perihepatitis, mammillations of the surface, and, upon section, fibrous gray tissue, enclosing numerous patent vessels, islets of yellow, soft, glandular tissue, and, in some places, intense congestion. In neither of these cases was there any suspicion of syphilis or malarial poisoning. Dr. Cazalis regards these cases as worthy of record on account of the extreme rarity of the occurrence of cirrhosis at such an early age. X.

QUININE IN SEPTICÆMIA AND TYPHOID FEVER.—Prof. Binz, of Bonn, has made a further contribution to our knowledge of the therapeutic effects of quinine. In a communication published in the *Berliner Klin. Wochenschrift*, No. 8, 1875, he alludes to experiments made by himself and others as to the effect of this drug in preventing a fatal result after injections of putrid material. He has found that in many cases (of dogs) experimented upon, a fatal result may be prevented by the administration of quinine, and even in those cases where death ensues its advent is much delayed. The temperature is lowered in all cases. As to men, Binz quotes Socin, who, at his suggestion, treated great numbers of patients during the Franco-Prussian war by quinine, in doses of from ninety to one hundred grains daily, with great success. Socin likewise suggests the simultaneous administration of alcohol, and says that he has obtained surprising results. Binz also alludes favorably to the use of quinine in typhoid fever, and quotes Liebermeister as saying that if he had to choose between the use of cold applications and quinine in a given case, he would choose the latter. As to the objection that quinine affects the intestines and causes bloody stools, Binz says that this result is due to the use of the sulphate, and recommends using the muriate instead. X.

ANÆSTHESIA PRODUCED BY ESMARCH'S BANDAGE.—Chauvel (*Centralblatt für Chirurgie*, No. 16, 1875) has made fifteen experiments: twelve on the liver, three on the upper extremities; putting on the bandage after having first ascertained the normal sensibility in each case. Diminution of sensibility was observed in each individual, not appearing immediately, but in five to twenty minutes. Insensibility appeared more quickly in the upper than in the lower extremities; its intensity depending on the tightness of the application: it first appeared in the peripheral portion of the trunk, and gradually spread to the upper regions. Insensibility to painful impressions was first noticed, but whether this extended beneath the surface was not ascertained.

In two operations for ingrowing toe-nail with the use of elastic compression very little complaint was made by the patient. In a case of ischiatic trouble the actual cautery was used after compression; anæsthesia, however, was incomplete. It is evident that elastic compression would fail in bringing about complete anæsthesia unless the ligature was placed so near the central portion of the limb as to cause other and inconvenient results. The conclusion is that, as an anæsthetic, compression cannot exclude chloroform or ether. X.

ANTAGONISM OF JABORANDI AND ATROPIA.—M. Vulpian has laid before the Académie de Médecine the result of his researches upon animals, showing the antagonism between these two drugs, and their inverse effect upon the biliary and pancreatic secretions.

Jaborandi excites these secretions actively, but an injection of sulphate of atropia causes their arrest, and the pancreatic fluid and bile are no longer observed to pass from the canulæ previously placed in the ductus choledochus and pancreaticus.—*Le Progrès Médical*, No. 12, 1875. X.

FOREIGN BODIES IN THE AIR-PASSAGES AND CÆSOPHAGUS.—Annandale (quoted by *Centralblatt für Chirurgie*, No. 16, 1875) remarks on the advantage obtained in searching for a foreign body in the larynx through a tracheotomy-wound, if support be given from the mouth by manipulation with the fingers. For the removal of foreign bodies from the bronchus he recommends, after tracheotomy and a deep inspiration, that the trachea be closed temporarily; the deep expiration following often drives the body out. Two cases are given by Annandale (see *Med. Times and Gazette*, February 27) illustrating the successful use of each of these methods.

Krishaber (*Séance de la Société de Chirurgie*, Nov. 11, 1874), in a case of foreign body in the cæso-phagus, caused the patient to drink a quantity of water, and then introduced a dry sponge at the end of a whalebone bougie. When the sponge had become swollen through absorption of water it was withdrawn slowly, and swept the cæso-phagus thoroughly from below upwards, carrying the foreign body, a piece of turkey-bone, with it. Dr. Duplay remarked, apropos of this treatment, that it would be difficult to employ when the patient could not swallow water, and that if the sponge became greatly swollen it might be difficult and painful to withdraw it. X.

PECULIAR APPEARANCES OF URINARY COLORING-MATTER FROM BLOOD COLORING-MATTER.—F. Hoppe-Seyler (*Centralblatt für Med. Wissen.*, March 27, 1875) observed some time ago that in treating an alcoholic solution of hæmatin with tin and hydrochloric acid—as by reduction—a coloring-matter of a peculiar appearance is noticed. This appears of a brownish-red color by transmitted light, and of a deep yellowish-green metallic lustre by reflected light. The author has now found that this coloring-matter is identical with Maly's hydrobilirubin or Jaffe's urobilin. Hæmoglobin itself gives, by similar treatment, a similar coloring-matter. It would appear from this that urobilin is an altered product of decomposition by reduction of the coloring-matter of the blood, and that bilirubin and biliverdin are intermediate products of this metamorphosis.

By this important discovery, the long-asserted origin of this coloring-matter from blood coloring-matter is proved. The amount of urobilin excreted within a given time would serve as a measure of the loss of red blood-corpuscles. X.

RELATIONSHIP OF PUERPERAL AND SURGICAL PYÆMIA.—E. Kleinschmidt, with the object of making a comparison between these diseases, brought together one hundred and eighteen cases of puerperal and eighty-three of surgical pyæmia. The result of the comparison showed certain essential differences. The puerperal affection was found to occur principally in the more youthful, while the surgical disease was more apt to occur in older persons. In the former the initial chill was usually (27 cases out of 40) found to occur in the first week, while in a similar number of cases of surgical pyæmia the first chill occurred in the first, second, and third weeks, which circumstances Dr. K., with C. Müller, explains by the possibility of infection before birth.

The greater frequency of renal abscess in puerperal cases (14.3 per cent. to 15 per cent. against 4 per cent. in surgical pyæmia) is not satisfactorily explained by the peculiarity of the injuries in child-birth.—*Centralblatt für Chirurgie*, No. 16, 1875. X.

DR. E. H. TRENHOLME reports (*Canada Medical Record*, p. 507, 1875) a case of traumatic tetanus successfully treated with chloral and bromide of potassium.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MAY 22, 1875.

EDITORIAL.

UNIVERSITY OF MICHIGAN.

MOST of our readers will, no doubt, remember our former editorial upon the University of Michigan. We have received from some of those connected with the institution courteous letters for our private enlightenment, and have perused the public reply of the *Peninsular Journal of Medicine* with care. Either the editor of the latter journal has not read the editorials which have appeared in the *Philadelphia Medical Times* during the last year, or else he is guilty of wilfully disregarding his own motto, "*Ars, ante omnia veritas.*" Any one who habitually glances over our columns must know that ever since the *Times* has been under the present editorial management it has been squarely and outspokenly opposed to the present system of medical teaching upon this continent, and has in no degree exempted the Philadelphia schools from its anathemas. Under these circumstances, to assert, by direct implication, that the editorial of the *Times* was written for the purpose of getting students for "a large Philadelphia medical school," with which the chief editor of the *Times* is so unfortunate as to be connected, is not only not courteous, but betrays a great want of wisdom.

As already stated, we have carefully read the editorial of the *Peninsular Journal of Medicine*, but we see nothing in it to require a revision of that which we have previously written. No new facts are developed. We perfectly agree with our Western

confrère, that the present system "is the fault of our whole system of education and laws on the subject of medicine, and of public opinion and practice." Certainly the University of Michigan did not originate this condition. The great mistake of its governors has been, as we conceived, the neglect of the opportunity peculiarly offered them of reforming the present system, or, in other words, their direct and unnecessary choice of large classes and present popular *éclat*, instead of the higher glory of being the mother of that newer education which must come so surely as the American people are progressing towards a higher civilization and a better government.

One of our correspondents has certainly given us a new idea which has some force in it, namely, that the University is not independent of its classes, because, as we understand it, it is supported by taxes, and the people who pay them would not be satisfied unless the classes were large. This seems plausible; but why does it not hold true in regard to the pharmaceutical, engineering, and other departments of the University? Are the people of Michigan such fools that they could not be made to understand that whilst a half-educated doctor is a pest to society, a thoroughly-educated, intelligent physician is a choicest blessing?

The editor of the *Peninsular Journal* refers to one more fact in confirmation of what he has said "of the thoroughness of the ordeal for the diploma of the University," i.e., in the Jefferson Medical College of Philadelphia, the diploma was granted, in 1875, to more than twice as many in proportion to the number in attendance as at the University of Michigan. There is a possible and very plausible explanation of this fact essentially different from that drawn with such effort by our Western *confrère*,—not that the Western diploma is of more difficult attainment, but that, the diploma of the Jefferson being considered more valuable than that of the University of Michigan, very many students prefer attending only one course in the latter institution, and come East to get their degree. The real reason, probably, is that the first course is taken at the University of Michigan to save expense, but that even the American medical student, during the last course, feels the necessity of that wide clinical teaching which can be obtained only in a great city.

THE London *Lancet* is in a state of great wonderment because a dentist of Scarborough has recovered his fees by suit, although he had an American

diploma. *En passant*, the London *Lancet* above all other journals ought to do its utmost to preserve the well of pure English from the defilement of slang, yet we notice in its report of the Exhibition of the Royal Academy, "There is no portrait or bust of any great gun in medicine." Is the art exhibition a place for artillery-trial, that one should expect to see there a gun "bust"?

A QUICK-WITTED Virginian details in the *Cincinnati Medical News* of May, 1875, the way in which he aspirated (successfully and repeatedly) the bladder of an old man suffering from enlarged prostate, by means of a Davidson's syringe and a hypodermic needle. A piece of india-rubber tubing was fastened to the needle, and another longer one to the nozzle of the syringe, and an attachment between the two made of a quill.

THE abortionists are beginning to reap a little of their deserts. The Dr. Dubois or Perpete, of whom we spoke some time since, has been found guilty of being "accessory after the fact," and a professional named Heap has very recently been executed at Liverpool.

WHO will free this country from the plague of medical schools? We have just received the announcement of the Penn Medical University of this city, with its lists of "alumni" and "alumnae." Truly the Americans are a long-suffering and much-suffering people.

CORRESPONDENCE.

LONDON LETTER.

[From our own correspondent.]

Medical Affairs in London—Mr. Erichsen on his American Visit—Why Sir Henry Thompson did not come—Sir William Fergusson and Sir James Paget at Norwich—The Debate on Vivisection—American Physiologists.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

IF, after a long silence, I may again take up my pen to renew correspondence, I will utilize part of my Easter holiday to tell you of some of the doings of London doctors during the last winter session.

I hardly know where to begin amidst the crowd of small matters that suggest themselves for discussion. To begin with, the earlier part of the session we had Mr. Erichsen's address on the experiences of his American tour. To say the truth, these were disappointing. Mr. Erichsen has a good reputation here for sound judgment, and, although the surgeon has never been on a level with his book in reputation, we expected that with so many advantages of observation, and so well-trained a critical capacity, Mr. Erichsen would have brought us home something new. He has, however, done nothing of the sort; whether he troubled himself

little about surgery, but more about the delights of hospitality and the pleasures of society and scenery, I cannot say, but the story which he was well qualified to tell, and which we hoped to have heard from him, has not been told. He has, however, paid a handsome tribute to the skill, capacity, and moral worth of the professional classes with whom he was brought into contact.

In missing the visit of Sir Henry Thompson you lost a guest who would probably have been more communicative on his return, and who has a considerable power of expression. The preliminary sufferings of sea-sickness on the way from Liverpool to Kingstown appear to have kept him away, and he compensated himself by a long tour in Italy, from which he did not return till November. Our English surgeons are thus beginning to emulate yours in their long vacations of months. Since he has come back he has resigned his office at University College Hospital, confining himself entirely to private practice. I believe that Mr. Erichsen also desired to resign, but was persuaded to hold on a little longer, as the Hospital could not have lost its two principal surgeons without incurring a serious loss of prestige.

If you desire a *vates sacer* who can with adequate eloquence describe what he sees, you must secure Sir James Paget; he is the orator of the profession; and his felicitous words gain added weight by the nice accuracy of thought which they convey. At present very few medical men here are at all acquainted with the extent of American medical institutions or the high standard of scholarship in the foremost ranks of your professional men. American degrees of a spurious and worthless kind are still freely sold here to quacks, and occasionally prosecutions, in which they are brought forward as an answer to charges of unqualified practice, sustain the prejudice.

Sir James Paget has been the object of attack here in consequence of his having sanctioned by his presence and approval the performance of certain experiments at Norwich, on a dog, by M. Magnan of Paris, with a view of demonstrating to the members of the British Medical Association the difference of action of alcohol and absinthe. Two "wild Irishmen," Professor Haughton and Mr. Tufnell, interfered,—Mr. Tufnell behaving with unqualified violence, and endeavoring to release the animal and stop the experiment. Mr. Tufnell had introduced a lay friend, and a policeman, I believe, was summoned. Ultimately Sir James Paget was appealed to; he sanctioned the completion of the experiment, on the ground that it "tended to the advancement of knowledge useful for the relief of disease." This scene led to a prosecution by the Society for the Prevention of Cruelty to Animals, and ultimately, although an acquittal was obtained, the decision was not one unequivocally favorable to the defendants. Mr. Tufnell holds for this year the position of President of the Royal College of Surgeons of Ireland; and, although he showed himself intensely ignorant of the subject in which he took so active a part, his official position produced a strong impression of his authority to speak for the profession. Unfortu-

nately, also, he found an unexpected ally in Sir William Fergusson. Although ignorant of the experiments, and of the relative facts of the action of alcohol and the essential oils, Sir William Fergusson allowed himself to be seduced into a general condemnation of physiological experimentation by the injection of fluids into the blood, and he declared that he considered it a barbarous and cruel proceeding.

The profession at large has viewed the course taken by Mr. Tufnell and Sir William Fergusson with great indignation and regret; not so much at the peculiarity of their opinions and the wild way in which they have expressed them, as at the reckless ignorance and intemperance with which they have publicly denounced methods of which they evidently do not understand the value, and experiments which they had not taken the trouble to study. The sequel of this "national prosecution" has been the commencement of a public agitation to impose legislative restrictions upon the practice of experimentation upon animals. A petition has been circulated, under the especial auspices, it is stated, of Mr. Hutton, the editor of the *Spectator*, Miss Frances Power Cobbe, Miss Burdett Coutts, and others, openly charging physiologists with the practice of daily barbarities of a wanton character. It is especially charged that American physiologists are guilty of cruelties which are revolting to humanity; that they are in the habit of daily demonstrating by vivisection of living animals, and of encouraging their students to similar cruelties. These charges were expressly refuted in the *Times* newspaper by Mr. Ernest Hart, who declared from his own knowledge, and from documents which he quoted, that the statements which have been published in every newspaper of London and throughout England by these memorialists as to the barbarity of American medical teachers and physiologists were "a foul calumny." In last week's number of the *Spectator*, however, Mr. Hutton again intimates that he adheres to the original view. I think it would be worth while for some of your American physiologists to look up the papers, and to send a formal repudiation of Mr. Hutton's charges to the *Spectator*, or, better still, to the *Times*; for the matter is not yet ended. A bill has, it is stated, been framed, and is now about to be introduced, with a view of penalizing physiological experiment; and, no doubt, during the discussion these stories of the daily horrors perpetrated by American teachers and their students will be again revived as examples of the moral degeneracy which is the consequence of practising vivisection! Dr. Bartholow's experiment on the exposed brain of a patient at Cincinnati has been this week trotted out at length in the *Spectator*, as an example of what is likely to happen to human patients in the future if this moral degeneracy be not checked. There is no greater intolerance than that of the humanitarian enthusiast towards people who know him to be wrong; and it has never been more strongly exhibited than in this case. A curious feature in this movement is that it is largely supported by sportsmen, on the ground of their great love of—dogs. The blood-

thirsty humanitarian this week expresses the delight which it would give him to "wing" any investigator who should for any purpose inflict suffering on a dog.

As this controversy has extended over many months and is still in a critical condition, and as it has largely included a discussion of American character as well as of medical proceedings, you must excuse me for allowing it to occupy so large a space in this letter.

I shall next week have much to tell you of our arranged scientific work for the next few months; of the progress of medical schools for women; of prosecutions of midwives for spreading puerperal fever, and of a surgeon for cutting away fifteen feet of intestine from a lying-in woman; *et alia multa*.

PROCEEDINGS OF SOCIETIES.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

WEDNESDAY, January 6, 1875.

DR. JOHN ASHHURST, JR., read a paper on *Excision of the Elbow*, narrating eight cases in which he had excised the elbow-joint, and appending a few practical remarks upon the rules which should guide the surgeon in determining to resort to this mode of treatment, upon the steps of the operation itself, and upon the after-management of patients.

He stated that excision of the elbow-joint when practised in persons past the middle period of life is attended with no inconsiderable risk. Thus, of fifteen cases of excision of the elbow-joint for disease in persons of forty-five years and over, collected by Dr. Hodges, of Boston, six proved fatal (two after amputation), while recovery was obtained in only nine. This rate of mortality (40 per cent.) is no doubt larger than that which attends amputation performed under similar circumstances, but the result of a successful elbow-joint excision is so satisfactory, enabling the patient to return to his ordinary occupation,—a most important matter for a laboring-man,—that the surgeon is fully warranted in recommending the graver operation in suitable cases. His cases were as follows.

Case I. Arthritis of left elbow in an elderly man; excision; death from exhaustion on thirty-third day.—This case having been already reported in the *American Journal of the Medical Sciences* for January, 1868, p. 42, we do not here reproduce it.

Case II. Excision of the right elbow-joint for disease in a young adult; death from tuberculous meningitis.—As a notice appeared in vol. iii. of the Proceedings of the Philadelphia Pathological Society (p. 157), we do not reproduce it.

With regard to the structural changes met with in this and similar cases, Dr. Ashhurst agrees with Barwell in regarding the so-called "pulpy" or "gelatiniform degeneration" as essentially the same as the granular change met with in cases of ordinary synovitis, the difference being that in the latter affection this granulation tissue undergoes further development, whereas in the cases now under consideration it remains in a rudimentary state. In fact, it occasionally happens that in one part of a joint the synovial tissue is found to be entirely replaced by organized intra-articular adhesions, while in another part of the same joint it may present the characteristic appearances of the gelatiniform change.

Case III. Excision of the right elbow; recovery.—Josephine K., aged 7 years, was admitted to the Children's Hospital on October 16, 1870, suffering from arthritis of the right elbow, the result of an injury received some six months previously. The joint was painful and tender, hot, and swollen, particularly at its radial side. After a fair trial of the effect of rest, with the administration of tonics and the topical use of soothing applications, excision was resolved upon, and on December 19, 1870, the patient having been etherized, the operation was performed, the joint being laid open by a single longitudinal incision, and the articulating extremities of the several bones removed with the "Butcher's saw." The joint was found to be full of pus, which gushed out as soon as the knife entered the articulation, the cartilages were eroded (especially over the head of the radius), and there was incipient caries of the subjacent bones. No ligatures were required, and, the edges of the wound having been brought together with leaden sutures, a strip of oiled lint was applied, and the limb placed at an angle of about 120° in a felt splint, which, however, bred maggots in the dressings, and was therefore replaced by a simple wooden splint on the third day. The after-progress of the patient was satisfactory; an abscess which formed in the neighborhood of the excision-wound was opened on January 31, 1871; and in the following March the splint was left off, and a simple soap-plaster and bandage substituted. The motions of pronation and supination were by this time fully restored, and there was slight power of flexion and extension, which could doubtless have been materially increased had the patient persevered in systematically exercising the limb. This, however, was not done, and ankylosis as regards flexion and extension eventually occurred. The patient was discharged from the hospital on April 15, 1872, but the last occasion upon which I saw her was in February, 1874, at which time the condition of the resected arm was very satisfactory, the limb, though stiff, being extremely useful, and the motions of pronation and supination being, as before remarked, perfectly restored.

Case IV. Compound fracture and dislocation of right elbow-joint in an adult; excision; death on seventh day from delirium tremens.—The subject of this case was a teamster, J. C., an Englishman by birth, and 51 years of age, who on March 27, 1871, was thrown from his wagon against a curbstone, sustaining such severe injuries as to necessitate his being brought to the Episcopal Hospital, where he was admitted shortly after the occurrence of the accident. Upon examination it was found that the patient had received a compound forward dislocation of the right elbow, with fracture of the olecranon; he strenuously objected to amputation, and, as the injury was limited to the parts entering into the articulation, it was determined to make an effort to save the limb by excision, though the intemperate habits of the patient (he confessed to half a gallon of beer daily) rendered the prognosis of the case less favorable than it would have been under other circumstances.

Ether having been administered, the joint was excised in the usual way,—viz., by making a single longitudinal incision between the olecranon and internal condyle, and, having turned out the ends of the bones, sawing them off with Butcher's saw. Two ligatures were required, a tent of oiled lint was introduced and the extremities of the wound closed with sutures, and the whole was then wrapped with a cloth dipped in laudanum, and the limb placed at rest on an obtuse-angled Physick's splint. The patient did well for four days, when he was attacked with delirium tremens, which carried him off on April 3, just one week from the date of the operation.

Case V. Excision of left elbow-joint for arthritis; recovery.—The patient in this case was a boy, R. A., aged 10 years, a native of Scotland, who was admitted to the Episcopal Hospital on January 11, 1872, suffering from arthritis of the left elbow, the result of an injury received one year previous. Excision was performed in the usual way (the joint being opened by a single incision made in the direction of the long axis of the limb) on January 18. Five ligatures were required, the excision wound was dressed with oiled lint, and the arm placed on an internal angular splint. The excised parts presented a good example of ulceration of the articular cartilages with incipient disease of the underlying bone. The splint was left off in the course of a few weeks, and care taken to prevent the occurrence of ankylosis by the systematic use of passive motion. The result of the case was in every respect satisfactory, the patient leaving the hospital on June 1, 1872, with the wound firmly healed, and with the normal motions of the part quite restored.

Case VI.—Excision of the left elbow-joint in a young child; splint left off after the eighth day; recovery.—The subject of this case, G. P., a boy 4 years of age, entered the Children's Hospital on August 8, 1872, suffering from disease of the left elbow-joint of one year's duration, believed to have originated from an injury, though the history of this was not very clear. Excision was performed in the usual manner on August 12, two ligatures only being required, and the wound being closed with sutures, dressed with oiled lint, and placed on a splint; this, however, was dispensed with after the eighth day, by which time the wound had united, and the parts were measurably consolidated, the limb from this time forward being simply supported in a broad sling. The principal seats of disease were the base of the trochlea and the greater sigmoid cavity of the ulna, at which points the cartilage had disappeared, and the subjacent bone was carious and deeply eroded. The progress of the case after the operation was satisfactory; an abscess which had formed in the neighborhood of the joint was opened on February 28, 1873, and the patient left the hospital on May 28 of the same year. The wound was firmly healed, the arm strong, and the motions of the part perfect in every respect.

In the next case the patient made a good recovery so far as the operation was concerned, but perished from the effects of constitutional disease nearly seventeen months subsequently.

Case VII. Excision of the right elbow-joint for destructive disease, the result of hereditary syphilis; recovery; death from syphilitic disease of the brain.—The patient in this case was one of those unfortunate children of whom we see so many in surgical practice among the poor of large cities, who enter upon life bearing about them the seeds of death, and who, after a few years of suffering, perish miserably, the victims of their parents' misconduct. J. S., a boy 6 years of age, entered the Children's Hospital on September 4, 1872, suffering from hereditary syphilis in an aggravated form. The record at the time of his admission shows that he had then necrosis of the left radius and of the lower jaw, with severe osteitis of the right humerus, extending to the lower epiphysis of the bone and threatening the integrity of the elbow-joint. A day or two after admission, a superficial exfoliation was removed from the radius, and on September 9, the patient being etherized, a large sequestrum was taken from the jaw, the portion removed extending to the articulation of the left side, and constituting about one-third of the lower maxilla. Under careful nursing and constitutional treatment, the patient's general condition now improved, and the jaw and left arm healed; the state of the right arm, however, became steadily worse, and in January, 1873, it

became evident that the elbow-joint was hopelessly diseased. Excision was accordingly resorted to on January 13, the operation being performed in the usual way, the wound dressed with oiled lint, and the limb laid upon a splint, which, however, was dispensed with as soon as the parts had become sufficiently consolidated. The progress of the case, so far as the operation was concerned, was satisfactory, the wound healing well, and the patient regaining considerable use of the limb; but fresh evidences of constitutional syphilis were not slow to manifest themselves. Gummatus tumors, which rapidly ulcerated, formed on the arm, on the shoulder, and on the side of the chest; the upper jaw became necrosed, and in October about one-third of its alveolar border was removed; finally, in June, 1874, symptoms of cerebral disease were developed, the patient lying in a stupor unless aroused, when he was delirious, but without excitement; and in spite of the administration of large doses of iodide of potassium, death, preceded by coma, took place on June 7. No post-mortem examination was permitted, but there can be little doubt that intra-cranial syphilis was the cause of the fatal issue.

The next case is illustrative of a condition perhaps more often met with in the knee than in the elbow, but which may, Dr. Ashhurst affirms, when occurring in either situation, in children at least, be treated by excision with the most gratifying results.

Case VIII. Excision of the left elbow-joint for partial ankylosis with recurrent arthritis; recovery.—This case occurred in a German boy, C. K., 6 years old, who was admitted to the Episcopal Hospital on March 24, 1873. A year before, the left elbow had received an injury, the nature of which was unknown, and for which no treatment had been employed. The joint, at the time of the patient's admission, was partially ankylosed, tender and painful on motion, with considerable thickening of the soft parts, and a distortion which simulated partial displacement of the radius. The part was constantly getting hurt, and every fresh injury left the limb more crippled than before. Excision was performed in the usual way on March 27, the lower epiphysis of the humerus being found to be separated and slightly carious, and the soft tissues of the joint presenting in parts the pulpy or gelatiniform change which has already been alluded to. The after-progress of the case was perfectly satisfactory; all the sutures were removed on April 1 (no ligature had been required); on April 18 the patient was allowed to get up; by May 17 the wound was almost healed, and the functions of the part were in a great measure restored; and, finally, on November 13 the patient was discharged from the hospital, cured.

Remarks.—Dr. Ashhurst enumerated the following reasons for the operation of excision of the elbow-joint: Grave wounds of the articulation; compound fractures implicating the joint; compound dislocation; arthritis which has resisted non-operative measures, or which has advanced to the stage of destructive disorganization, —and particularly arthritis of the gelatinous variety; fibrous ankylosis when complicated by frequently-recurring attacks of inflammation of the joint; and bony ankylosis, when the limb is in such a position as to render it useless to the patient. The operation is, indeed, recommended by some writers in cases of bony ankylosis in a good position; but Dr. Ashhurst had never felt justified in resorting to it under these circumstances.

Excision of the elbow may be resorted to with much greater freedom than excision of other large joints, because the mortality after the operation is so moderate, and the result of a successful excision so much better

as regards the utility of the limb than the cure obtained by the occurrence of ankylosis.

The chief contra-indications to excision of the elbow have regard to the *age* of the patient and to his *constitutional condition*, particularly in respect to the existence or non-existence of visceral disease.

The influence exercised by the *age* of the patient upon the result of the operation is shown by the following recast of Hodge's table of 119 cases of excision of the elbow for disease of the joint:

AGE.	RECOVERED	DIED.	AMPUTATED.	NOT TERMINATED.	TOTAL.
Under 10	3	1	2*	...	6
10 to 20	27	3	2*	...	32
20 to 30	28	3	6*	2	39
Over 30	26	7	5†	...	38
Not stated	3	1	4
Aggregate	87	15	15	2	119

This table shows that while the mortality for all ages under thirty is but about 9 per cent. (77 cases, 7 deaths), the mortality for all ages over thirty is almost 24 per cent. (38 cases, 9 deaths).

The *constitutional condition* of the patient exercises a very important influence on the result of the operation. There is perhaps less immediate risk attending an excision of the elbow than an amputation of the arm, on account of the comparative freedom from hemorrhage in the case of the first-named operation; but the much longer period required for convalescence after excision exposes the patient for a longer time to the risks of erysipelas, pyæmia, etc., and gives opportunity for the development or aggravation of tuberculous and amyloid degenerations.

Hence, should there be reason to suspect serious disease of the lungs, liver, or kidneys, the operation of excision would be so far contra-indicated, and, if under these circumstances any interference should be required, preference should, as a rule, be given to amputation.

Except in his first case, in which he adopted the H incision of Syme and Butcher, Dr. Ashhurst has uniformly employed and much prefers (as originally suggested by Park) a single longitudinal incision on the inner and posterior side of the joint. With a little practice this mode of operating is found quite as easy as any other, while it has the great advantage of leaving a linear wound which has no tendency to gape.

The length of the incision may vary from two to five inches, according to the size of the arm. Its direction should, of course, correspond with the long axis of the limb, and it should pass on the inner side of the olecranon and a little on the radial side of the ulnar nerve. In order to guard against loss of the power of extending the limb, Prof. Spence recommends that the triceps tendon should be divided by means of an incision in the form of an inverted Λ , while with the same object Mr. Maunder takes care to respect those fibres of the tendon which are inserted into the fascia of the fore-arm. Either of these plans may be adopted with good result. Prof. Sayre's plan of leaving the portion of the olecranon to which the tendon is attached, Dr. Ashhurst feared, would increase the risk of ankylosis.

The points of most importance in the operation are to save the ulnar nerve from injury, and not to interfere with the tubercle of the radius, so as to preserve the attachment of the biceps muscle. In excisions for

* Recovered after amputation.

† Two recovered; two died; result of one not mentioned.

‡ This includes the two cases which terminated fatally after amputation.

disease, the nerve need give no trouble, for it is so imbedded in inflammatory tissue that it can be readily drawn from its position in the groove between the olecranon and internal condyle, and held to the inner side, and indeed need not be seen during the whole operation. In traumatic cases more difficulty is, of course, experienced; though even here a little care suffices to avoid any untoward accident. Provided that the tubercle of the radius is preserved, the more bone (within certain limits) that is removed, the better will be the result of the operation; the risk of ankylosis is much greater than that of flail-like union, and hence the saw may be used freely, without any dread of interfering with the future utility of the limb.

In the *after-treatment* of a case of elbow-joint excision, the most important point is to guard against the occurrence of ankylosis; and this may best be done by abandoning the splint at a very early period,—as soon as the external wound has united and the inflammatory swelling which always follows the operation has subsided. Some writers, indeed, go so far as to recommend that no splint at all should be employed, but that the limb should be, from the first, simply laid upon a pillow. This advice seems to Dr. Ashhurst injudicious, particularly in the case of children. By putting the limb at rest upon a well-padded splint for a week or ten days, the risk of consecutive hemorrhage is greatly diminished, the inflammatory action which follows the operation is lessened, and the part is placed in the most favorable condition for rapid repair.

The chief *statistics* of the operation are as follows: Heyfelder and Boeckel have tabulated in all 203* cases of total and 79 cases of partial excision of the elbow. The result in one of the cases of total excision is not stated, but of the remaining 202, 8 were saved by amputation, while only 24 terminated fatally, giving a

death-rate for the operation as performed for all causes of less than 12 per cent. If excisions for chronic disease only are considered, the figures are 145 cases, with 20 deaths and 7 consecutive amputations, a mortality of over 13 per cent. The 79 cases of partial excision gave 8 deaths and 3 amputations, a mortality of but little over 10 per cent. Hodge's statistics, which, though less extended, are probably more accurate, give a slightly different result; of 119 cases of excision for disease, 15 terminated fatally and 15 required subsequent amputation, death moreover following in 2 of the latter; these being included in the list of fatal cases, the death-rate is found to be over 14 per cent. It is to be observed, however, that these figures embrace both complete and partial excisions, as well as 16 cases in which it is not mentioned whether the whole joint was or was not removed. If the complete excisions alone are considered, the figures are 82 cases, with 7 deaths and 7 amputations (one fatal), the mortality thus being but a little more than 10 per cent. On the other hand, 21 partial amputations gave 5 deaths and 3 subsequent amputations, a mortality, therefore, of nearly 24 per cent. Ollier has laid great stress upon the importance of preserving the periosteum in excisions of the elbow, and has reported 35 cases of the sub-periosteal operation, with 30 recoveries and 5 deaths, a mortality of over 14 per cent.

When performed for traumatic causes, the operation in civil life would appear to be ordinarily attended with very little risk, 21 cases referred to by Dr. Hodges having given but one death, and that "from causes in no way attributable to the excision." In military practice the results are not so favorable, 286 terminated cases noted in "Circular No. 6" having given 62 deaths, a mortality of nearly 22 per cent. It is, notwithstanding, in military practice that excision of the elbow has gained some of its most brilliant successes.

Summary of the Cases detailed in the Preceding Paper.

No.	NAME, SEX, AGE, ETC.	NATURE OF AFFECTION FOR WHICH OPERATION WAS REQUIRED.	RESULT; DURATION OF TREATMENT AFTER OPERATION.	REMARKS.
1	B. F., male, 56, blacksmith.	Arthritis of left elbow.	Died; 33 days.	Death from exhaustion.
2	J. D., male, 25.	Gelatinous arthritis of right elbow.	Died; 19 weeks.	Death from tuberculous meningitis.
3	J. K., female, 7.	Arthritis of right elbow from injury.	Recovered; 16 months.	Ankylosis as to flexion and extension.
4	J. C., male, 51, wagoner.	Compound fracture and dislocation of right elbow.	Died; 7 days.	Death from delirium tremens.
5	R. A., male, 10.	Arthritis of left elbow from injury.	Recovered; 4½ months.	Normal motions of part restored.
6	G. P., male, 4.	Arthritis of left elbow.	Recovered; 9½ months.	Normal motions restored.
7	J. S., male, 6.	Right elbow destroyed by constitutional syphilis.	Recovered from operation; died 17 months subsequently.	Death from syphilitic disease of brain.
8	C. K., male, 6.	Partial fibrous ankylosis of left elbow, with recurrent arthritis.	Recovered; 7½ months.	Normal motions of part restored.

GLEANINGS FROM OUR EXCHANGES.

A MEDICO-LEGAL CASE (*Boston Medical and Surgical Journal*, May 6, 1875).—The following appearances were observed at a post-mortem examination of the body of a woman who was struck, while lying on the track, by a train of cars, and who it was afterwards found had had some altercation with a man early in the evening of the day of the accident. They are interesting as an illustration of the value and importance of a thorough autopsy, even in cases where the cause of death seems at first sight to be very apparent.

"Over the right malar bone there was a lacerated wound one inch in length. A similar wound extended across the nose, which was crushed and forced to the left. Beneath the left eye there was another laceration,

about one inch in length. These wounds were surrounded by bluish-red discolorations, which when incised showed very slight extravasations. The skin of the face in the immediate neighborhood of the wounds was slightly stained with blood. Upon the anterior and lateral portions of the neck were several irregularly-shaped yellowish-red marks, which upon being incised disclosed no extravasations. There was an irregular opening about four inches in diameter, with ragged and thinned edges, located in the skin of the chest about four inches below the middle of the right clavicle. About this opening there were several dark-reddish patches. The right arm was torn from the shoulder, and hung by a few shreds of skin. The left arm was entirely separated from the body about four inches below the shoulder. There were patches of ecchymosis in the substance of the scalp over the posterior portion of the occipital bone and also over the left temporal bone. The vessels of the scalp were congested. The vessels of the dura mater and pia mater were exceed-

* Incorrectly numbered in Boeckel's translation of Heyfelder's *Treatise* as 208.

ingly congested. The cerebral sinuses were full of dark semi-fluid blood. All the vessels of the brain were engorged with blood. There was no fracture of the base of the skull. The superior maxillary, malar, and nasal bones were fractured and displaced backward and to the left. The lower jaw was fractured. In the connective tissue anterior to the fourth and fifth cervical vertebrae, between the cornua of the hyoid bone, and also posterior to the larynx, were decided clots of blood. The lining membrane of the trachea was of a bright-red color and intensely congested. Anterior to the body of the cricoid cartilage, commencing at the lower border of the vocal cords, there was a marked ecchymosis. The spinal column, from the seventh cervical to the first lumbar vertebra, and the walls of the chest, were crushed. The thoracic viscera were ground to fragments. Small portions of the lung only could be identified; these portions were of an evenly-diffused dark-purple color, and excessively congested. The vessels of the mesenteries were full of dark blood. The vena cava ascendens was also distended with blood. All the other organs were examined and found to be in a healthy condition."

In the opinion of the physicians, death was caused by asphyxia, resulting from strangulation, produced at some period anterior to the passage of the railway-train over the body.

HOT BATHS (*Medical Press and Circular*, April 7, 1875).—The following practical rules have been suggested by Prof. Lasegue:

No hot bath ought to exceed twenty or thirty minutes in duration.

The initial temperature ought always to be lower than the final temperature.

The increase of temperature ought always to be gradual.

The maximum temperature is usually 103°, but 108° can easily be tolerated if the patient does not remain in this temperature longer than eight or ten minutes, and if the unpleasant sensation produced by the vapor on the part of the body which is not immersed is avoided. On leaving the bath the patient goes to bed, and soon loses the sensation of unusual heat. Cold douches, which are so agreeable after hot-air baths, are not well borne after hot baths.

Lasegue has found a prolonged course of hot baths very useful in chronic rheumatic arthritis. Under their influence the movements of the articulations have become less difficult and painful. A similar mode of treatment has been found useful in chronic abdominal complaints, such as protracted diarrhœa, and even in obstinate chronic bronchitis.

AN APPLICATION TO PREVENT PITTING OF SMALLPOX (*British Medical Journal*).—Dr. J. Ward strongly recommends the application of honey two or three times a day by the aid of a camel's-hair pencil for more general and extensive trial, inasmuch as it seems to present many of the qualities desired,—viz., exclusion of the air, preserving the parts permanently moist, and lessening of the local irritation; while it is an application gratefully detergent and harmless, permitting the transpiratory function of the skin. The domestic application of honey to the skin of the hands and other exposed surfaces of the body, when rough or cracked from the effects of frost, etc., is more or less known, and, when tried, fully appreciated. It is not unlikely that, when applied early and repeatedly to a more extensive surface than that usually exposed to the air, and even to the roots of the hair, its primary and somewhat unpleasantly sticky feeling would speedily give place to a sense of general soothing and comfort, from its effect of allaying the irritation which is so troublesome a feature in smallpox.

A STYLE FOR OBSTRUCTION OF THE LACHRYMAL APPARATUS (*The Lancet*, April 24, 1875).—Mr. R. Taylor has introduced a form of style which has many advantages over all others, and which he has used constantly and with great advantage. This style is a straight piece of silver to fit the nasal duct, having at right angles to it, at the upper end, a small arm about three-eighths of an inch in length; it is introduced along the slit-up lower canaliculus, through the lachrymal sac, into the duct. The little horizontal arm lies in the channel of the canaliculus, which it keeps open, and prevents the style from slipping out of sight, allowing ready removal when necessary. The canaliculus is slit up in the usual way, and he then either dilates for a short time with the ordinary probe and then puts in the style, or more generally, where the case is a straightforward one, introduces the latter at once. Different sizes are required. The style requires to be taken out and cleaned occasionally, and if there be any irritation set up by it, which is not common, the removal of it for a day or two is generally sufficient to allow it to be worn with ease. Patients are so comfortable while wearing it that they often neglect to appear at the end of a month or six weeks to have the instrument removed.

TREATMENT OF WHOOPING-COUGH (*American Practitioner*, May, 1875).—Wild claims that he can cure every case of whooping-cough within eight days by the following treatment: the patient is not to leave his room, and at every access of coughing is to place before his mouth a small piece of cloth folded several times and wet with a teaspoonful of the following solution: ether, sixty parts; chloroform, thirty parts; turpentine, one part.

ERYSIPELAS, SEPTICÆMIA, PYÆMIA (*The Lancet*, April 10, 1875).—Mr. Jonathan Hutchinson has demonstrated that erysipelas, which is so potent an agent in producing puerperal fever, is *not* a specific fever; that it is simply a local inflammation, to which all its febrile and general symptoms are superadded,—a view supported by its unilateral character, by the absence of any incubative period, and by it being possible to cut short its extension by appropriate treatment. In this respect it resembles inflammation of the uterus. The term "septicæmia" should be limited to poison introduced into the blood from the patient's own tissues, which may have been primarily inflamed by irritants derived from without, or even without any external cause whatever; while "pyæmia" has its sole origin in a suppurative phlebitis.

MISCELLANY.

A LADY who is ardently opposed to vivisection, and who would like to have the letter V branded on the right hand of every vivisectionist, was about to have a dinner-party of ladies and gentlemen of her own opinion. The night preceding this great occasion she ordered of her intelligent fishmonger a crimped skate, and in the afternoon of the important day was astounded by the announcement of the cook that the fishmonger, Mr. Donald (his further name we have pledged ourselves not to divulge), had failed to send in the fish. In dudgeon our philanthropic lady, whose impulses were always ahead of her reason, whipped on her bonnet and away to the man of the marble slab and cold-blooded viands. She found him putting the finishing touch to the skate, and, having first rated her experimentalist for his delay, went on, "peppery like," as Donald noted, to find fault with his work. Donald, of

course, laid the delay on the market, and as to the fault in the crimping, he urged that if he couldn't get the animals until they had hardly a drop of life in their bodies, how could they be expected to crimp like real live ones? The lady, convinced by Donald's arguments, or fearing further delay, calmed down, and, begging the fish might be sent around immediately, was about to leave the shop, when her eye caught sight of a small moving object on the side-counter. "Why, Mr. Donald," she exclaimed, "what is this? it is moving like a watch." "That, madam," replied Donald, "is the heart of the skate; it's laid aside for a medical gentleman, who studies the heart, to see how long it will just throb." The effect on the lady was electrical. "A vivisectionist!" she almost screamed; "and you, Donald, minister to his barbarities?" Donald stood aghast; he expected next moment to hear the request that he might send in his bill. But a new light seemed to fill his visitor's face; she spoke persuasively, yet decidedly. "Donald," she asked, "who is this wretch? We may now establish a case." Donald was on guard; he was between Scylla and Charybdis, for the doctor was as good a customer as the philanthropic lady; but he was equal to the occasion. "Madam," he replied, "I ken naething o' the gentleman, mair than he's student-like, grave and serious. When he ca's to-day for the heart, if I dinna mind his name and address, I'll e'en ask him." "Do, Mr. Donald, pray do," she answered, and, seeing a hansom cab passing the door, hailed it instant. Donald went to open the folding doors of the vehicle for her, and heard the conversation with the cabman. "Drive me quickly to the R. S. P. C. A." "To the Arispiciary," says the driver, spelling it to himself. Then down into the cab, "Is it the new resterong at 'Ighbury, mum?"

"No, it's the animal place; take me, take me to Mr. Colam!"

Cabby,—who thought he now saw his way,—down again into the cab, "At the Zoo, mum, I suppose."

"The Zoo! No; though I believe that's a bad place enough. Jermyn Street."

And away, as fast as a wearied horse—keeping a hasty lady from friends expected at dinner—could speed under influence of jerk of rein and cut of whip, away she sped.

Meanwhile, Donald, surmising that his shop might by-and-by be under uncomfortable surveillance, picked up the still beating skate's heart, put it into a gallipot, and away himself with it to his patron the doctor. Could he see the doctor for just a second? He could, and was shown straight into the study. The man of science was busy fitting up a reoscope when Donald entered.

"I brought ye, sir, the skate's heart; it seemed to me to be stopping a wee, so I brought it myself."

"Thank you much," answered the doctor, taking his treasure and watching the motion. "It's a strange phenomenon."

"Mair strange than ye yerself ken, doctor," said Donald, with a knowing look.

"All God's works are, Mr. Donald," was the solemn

reply of the philosopher. "Thank you again, and good-day."

And Donald, thinking he had done enough, withdrew. He had saved his patron from being possibly followed by a detective, which was what he wanted.—*British and Foreign Medico-Chirurgical Review*, April.

NOTES AND QUERIES.

PHILADELPHIA, May 3, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

SIR,—In reply to the letter of Dr. J. J. Leiser, which appeared in the number of May 1, I would state that I have used hydrate of chloral in five cases of puerperal convulsions with perfect success; in two cases other means had proved ineffectual.

In the administration of chloral I follow the following simple rules.

1. To bleed if the patient is plethoric,—not with any idea of its arresting or decreasing the convulsions, but to relieve the engorged vessels, which done, renders the stomach more absorbent.

2. To give \mathfrak{v} of chloral every fifteen minutes in large quantity of liquid, and, if the patient cannot swallow, give \mathfrak{ss} of chloral by the rectum every half-hour, till convulsions cease.

3. Combine the chloral with some alkali (I usually use bromide of potassium), for I have found to exist a certain condition of the stomach or blood which does not allow the decomposition and absorption of chloral to take place readily unless combined with an alkali. In my last two cases this combination was made after the chloral alone refused to act promptly.

The above are the simple rules which guide me in the administration of chloral, and I have as yet not been disappointed in a single case.

I use chloral extensively in my obstetrical and uterine practice, and wish no better medicine of its class.

In regard to hydrate of chloral, we have at present on the drug-market two specimens, *one a perfectly worthless article*. The good drug is recognized at once by its pungent odor and smell of walnut; it is also in perfectly white crystals, and if examined by being held up before the eye the crystals will appear almost transparent.

The other article is of a yellowish-white, sometimes entirely white color, uncrystallized, exceedingly pungent, having the irritating odor of chlorine, and a smell somewhat like cucumbers.

Care should be taken by the physician in prescribing to call distinctly for the first article, and I am certain there will be less disappointment.

In looking over the case of the doctor, I find that he gives twenty grains of chloral at the start, then gives in *half an hour* thirty-five grains, giving in the hour about *fifty-five* grains, where I would have given *eighty grains at the lowest*. In an hour he repeats the *thirty-five* grains, which is *forty-five* grains less than I would have given. He gives in all one hundred and twenty-five grains in eight hours; I would have given, according to my method, six hundred and forty grains. This quantity *would not have been given*, for I am firmly convinced that had the doctor repeated at short stated intervals his doses, the convulsions would have ceased before *half the quantity* had been used. In my first case I used two hundred and twenty grains in eight hours, almost double the quantity used by Dr. L.; it was only after the *eight scruples* had been taken that the medicine seemed to act.

I therefore think that the want of success lies with the doctor in not giving freely the chloral, and not from the want of action in the medicine. When chloral is given in puerperal convulsions it must be given boldly.

Yours respectfully,

EUGENE P. BERNARDY, M.D.

1011 WALNUT STREET.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MAY 11, 1875, TO MAY 17, 1875, INCLUSIVE.

KINSMAN, J. H., ASSISTANT-SURGEON.—Assigned to duty at Fort Ripley, Minn. S. O. 83, Department of Dakota, May 11, 1875.

HEIZMANN, C. L., ASSISTANT-SURGEON.—Leave of absence extended three months. S. O. 89, A. G. O., May 12, 1875.

PAULDING, H. O., ASSISTANT-SURGEON.—Assigned to duty at Fort A. Lincoln, D. T. S. O. 78, Department of Dakota, May 6, 1875.

ORIGINAL LECTURES.

CLINIC

OF PROF. D. B. ST. JOHN ROOSA.

Reported by J. M. HARVEY, M.D.

Delivered May 4, 1875, at the University Medical College, N. Y.

GENTLEMEN,—I want to recall to your minds the case of atrophy of the optic nerves, in a man who came here last week and confessed to very intemperate habits in the use of alcohol and tobacco. I made, by means of the ophthalmoscope, the diagnosis of atrophy of the optic nerves. You know the optic nerve enters the eyeball a little on one side of the centre. Its surface after entering the eyeball is called optic papilla or disk, and is a blind spot at all times; that is, no image is formed upon it; therefore, if we could imagine such a state of things as atrophy of this nerve-entrance only, while its fibres which pass into the retina are intact, you might well ask, how will there be any blindness? What difference would it make if the optic nerve-entrance be atrophied? Such a case has been lately attending at the Manhattan Eye and Ear Hospital. The ophthalmoscope shows not only whiteness of the papilla, but actual shrinkage of tissue and lessening in size of the vessels, with excavation of the disk, and yet the vision, since he has been treated for syphilis, which was the provoking cause of his optic neuritis and subsequent atrophy, has increased to the normal standard. From this entrance go out transparent fibres which make up a part of the retina. Now, if we have this optic nerve atrophied, and the fibres that convey impression to the brain become affected, then vision is impaired. A man may have considerable atrophy of the nerve-entrance, but so long as these fibres that pass out into the retina are not interfered with he may have very good sight; in the present case we found vision very much reduced, so that it was only about $\frac{2}{100}$ on each side, but there may be decided atrophy of the nerve-entrance and yet the vision be $\frac{2}{10}$.

We call this disease *amblyopia potatorum*, from drinking, or *amblyopia ex abusu*, from abuse of any of the stimulants or narcotics. It is usually a neuritis in its first stages. The treatment is, in the first place to abandon the habit which produced the trouble, and in the second place to stimulate the nerve. You remember we advised that man to give up the use of tobacco and alcohol, and to use strychnia. The object of the strychnia was to stimulate the vessels to produce such action as will fill up these little lateral blood-vessels of the disk which have become void of blood, for it is anæmia which causes this tissue to shrivel and lose its power of conveying impressions.

Atrophy of the optic nerve may be produced by very many causes, and I do not think true atrophy of the nerve is one of the frequent results of the

abuse of narcotics and stimulants. A man may get a blow on the back of the head which may cause congestion of the brain, and the blood in the vessels pressing upon the optic nerve may cause the circulation in the nerve to be diminished, or hemorrhage from these vessels may cause a destructive or injurious pressure. A tumor may arise from the base of the brain, or, as sometimes happened during the late war, a man may be shot in the head, the ball passing across the optic nerve; the result will of course be atrophy of the stump of the divided nerve. Any disease of the brain which produces pressure on the nerve or destruction of its continuity, if the pressure be continued long enough, will cause atrophy.

I was called a few days ago, by a member of the class, to see a young woman who had a chill and complained of pain in her eyes, and, taking my ophthalmoscope and looking in upon the eyes, I found she had acute inflammation of the optic nerve-entrance descending from the brain (*neuritis optica descendens*), and unless that passes away very quickly the tissue will be so pressed upon that atrophy will result. Acute inflammation of a nerve is not always followed by atrophy, however, for many cases of neuritis are recovered from without any marked changes in the nerve-tissue. Atrophy of nerve-tissue in one part of the body is exactly the same as in any other part. Why does not every one who uses tobacco in excess get neuritis and subsequent atrophy of the optic nerve? I cannot answer that question, any more than I can tell why all persons who use alcohol to excess do not die of delirium tremens. Some persons who use alcohol to excess live to old age; so also it can be said of some who use tobacco to excess: they live to old age with apparently no impairment of their organs. We do know, however, that the excessive use of tobacco and alcohol sometimes produces neuritis, and that by the entire abandonment of the habit a recovery is often secured.

There is just one thing to be said about the use of the ophthalmoscope in the diagnosis of disease. By many general practitioners it is considered a very complicated instrument. I grant that to understand the principles upon which its use is based requires a very considerable knowledge of optics, but, practically, it is a very simple instrument; it is simply a reflector by which to illuminate the back part of the eye, and a man may learn to make a diagnosis with its aid before he has mastered the principles upon which its use depends.

Case I.—This case (*strabismus convergens*) speaks for itself. This little girl has got strabismus or convergent squint. You will see that one eye runs past the optic axis so as to cause great deformity, and the images cannot fall upon the same spot in the two eyes; consequently if she sees with each eye there will be one image in one eye and another image in the other eye; but probably one image is suppressed or disregarded, and she sees only with one eye at once.

There is but one thing that will cure the strabismus, and that is an operation.

The mother says her child was not born with

squint, but that it occurred soon after birth. This is a very natural mistake, but nevertheless a mistake. The conditions for the strabismus existed at birth, although the squint did not show itself until the eyes began to be used on objects near the eye, or when the eyes were steadily fixed upon a near object. Convergent strabismus results from a shortened condition of the eyeball, and it occurs at a very early age, as soon as the patient begins to use the eyes on objects near at hand; and although it may be said persons are not born with squint, it is nevertheless true that they are born with that condition which produces this trouble. The shortness of the eyeball prevents the patient from being able to see distinctly at any distance, but such persons soon find that they can see more distinctly if they excessively converge the eyes, and in that excessive convergence one eye begins to shoot by the other, and then they have such a state of things as is represented in that diagram, the images not being received on corresponding parts of the retina. I examined this child's vision, and found it more defective on one side than on the other. This defect occurs as a consequence of the want of development of the eyeball,—hypermetropia. The operation for squint essentially consists in dividing the muscle and causing it to insert itself farther back on the eyeball, where it will have less power and the patient cannot converge the eyes so much.

The instruments necessary for a squint-operation are, first, one that will keep the eyelids open,—a spring speculum; second, an instrument that will hold the eyeball,—a pair of fixation-forceps; third, a pair of forceps to take up the conjunctiva; fourth, a pair of scissors with delicately rounded points, with which to cut through the conjunctiva and theca; fifth, a strabismus-hook for taking up the tendon; and sixth, a pair of scissors with which to divide the tendon.

The strabismus is so great in this case that the muscle will have to be divided in each eye.

[Operates.]

That is an operation, gentlemen, which all of you may easily repeat on the cadaver, and observe every part except the bleeding.

When this child began to squint, if it had been possible for her to tell her sensations she would have told you that she saw double,—one image with one eye, and another image with the other eye. This double vision is very annoying, as any one of you may know if from any cause you ever experienced it. In order to get rid of this annoying double vision the patient soon learns to suppress the image of one eye, and, as a result of this suppression, you will almost always find that the vision is better in one eye than in the other.

As the operation for squint consists in dividing the muscle and causing it to insert itself farther back on the eyeball, you may ask, why does not the squint return after the muscle has inserted itself and again become powerful? It will return in many cases unless the shortened condition of the ball be corrected by glasses that have the effect of lengthening it,—by a convex glass.

Case II.—This gentleman is a member of the class,

and he has done me and you a great favor by allowing his case to be presented before you for examination. Age 26; had trouble in ears thirteen or fourteen years. The gentleman says he went in bathing, and after coming out of the water he felt bubbles in his ears, and his hearing was impaired.

This was still-water bathing. In surf bathing there is great danger, from the force of the waves striking the membrana tympani and breaking it. There is always danger, in any kind of bathing, of water getting in the ears, soaking through the membrane, and setting up congestion and inflammation of the tympanic cavity. What this gentleman had was congestion of the tympanic cavity, caused by the presence in the ear of a large quantity of water which had soaked through the membrane. While bathing we have all had the experience of getting water in our ears, and we are all familiar with the boys' method of getting it out,—i.e., jumping on one foot until the ear is shaken dry.

There is but little if any impairment of hearing in this case, consequently he could have no suppuration of the middle ear, and what he is now troubled with is eczema of the external auditory canal. The great remedy for chronic irritation of the external canal is warm water three or four times a day, and next to that sulphate of zinc or alum. If you see the patient yourself, you might apply nitrate of silver in solution by means of a little cotton on a cotton-holder. The gentleman before us does not need any constitutional treatment. I should say that your class-mate was a perfectly healthy man, and that the eczema occurs from causes entirely local, and local treatment as suggested above will cure it.

ORIGINAL COMMUNICATIONS.

WHAT CONSTITUTES A LIVE BIRTH?

BY JOHN J. REESE, M.D.,

Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania.

THE question, What constitutes a live birth? has an important twofold medico-legal application. First, in its *criminal* relation to infanticide; and secondly, in its *civil* bearing to the transmission of an estate from a deceased wife to her husband, through issue born alive.

A very different answer to the above question would be given by the non-professional and the professional person. In the estimation of the former, life in the new-born babe is evidenced only by the full and active play of all the functions and organs of its body. If it has come into the world without exhibiting voluntary movements and without visible respiration (and consequently without the traditional cry), albeit having a pulsating umbilical cord, a throbbing heart, and a distinct pulse, he would probably pronounce that the child is not really alive,—that is, that it has not a separate, independent existence apart from its mother; but that it merely carries in its body the faint remnants of its former foetal life, which are now rapidly flickering away.

On the other hand, the professional expert will tell us that *any one* satisfactory evidence of life is sufficient to establish its existence, both physiological and legal.

Let it be premised that by the term *live birth* the law understands "the complete extrusion from the mother of a living child," with or without the severance of the cord. In the case of an alleged infanticide, where proofs of the crime can be obtained solely from the inspection of the dead body, the chief evidence of previous life is derived from the *hydrostatic test* of the lungs; and this, unfortunately, is not always reliable. But in the civil case, which has reference to the transmission of an inheritance through a child born alive, the proofs of the live birth can readily be furnished by the attending physician, as also by other witnesses who may have been present at the delivery. In this latter case, no post-mortem examination is necessary, since the other proofs of life are far more satisfactory and complete.

It is to the latter aspect of the case (the civil) that I propose briefly to direct attention in the present article. By the old English law which has been in operation for centuries, and which is recognized at the present day in several of the United States, the husband of a deceased wife who dies seized of an inheritance acquires a life-interest in such inheritance, *provided* there was issue born alive. In such a case, the husband is technically said to inherit by "tenancy of the courtesy of England;" he is called "a tenant by courtesy." In the State of Delaware, which still retains the old English law on this subject, an important case lately occurred in which this principle was involved. The case (*Stout vs. Killen*) was tried in Dover, May 4, 1875, before the Superior Court of Delaware, the Hon. Judge Gilpin presiding, on a writ of ejectment brought against the defendant for the recovery of a property that had passed into his possession, as "tenant by courtesy," on the death of his wife some years previously, through an infant alleged to have been born alive, but which survived but half an hour. The plaintiffs (the wife's heirs-at-law), on the other hand, affirmed that the child was not born alive, and, consequently, that the estate did not pass to the husband. Here the whole case virtually turned upon the question of the live birth, and this, of course, involved the important query of what constitutes a live birth.

Two highly respectable physicians who attended the lady in her confinement testified that the labor was a protracted and difficult one, requiring the use of the forceps. The patient, moreover, had convulsions. The child was large and fully developed, the chest was rounded, the lips were ruddy, the general color of the body natural (not livid). The umbilical cord distinctly pulsated for about twenty minutes after complete delivery, when it was cut. The heart and temporal arteries beat distinctly all this time, *and continued so to do for five or six minutes after the severance of the cord.* There was no perceptible respiration, and of course no cry; nor were any spontaneous movements of the body observed. All the usual restorative measures were practised, but without effect; all evidences of life

ceasing about half an hour after the birth. Both the physicians testified that they regarded the child as born alive.

As one of the expert witnesses called for the defence, I had no difficulty whatever in giving an affirmative answer to the question, Was this child born alive? and in this I was ably supported by Prof. Penrose, of the University of Pennsylvania, and also by several distinguished physicians of Dover; and I based my opinion upon the following data:

It has long been a settled point in law, founded upon a recognized physiological fact, that respiration (or crying), although an important evidence of live birth, is by no means the *only* evidence. It is admitted that a child may be born and die without breathing; so that the wilful destruction of such a child is just as much murder as if it had cried lustily and moved its limbs vigorously. What the law requires in such cases is simply *proof of life*, not proof of respiration. Now, if life can be proved by other means than by respiration, the law's demands will be satisfied. I think we must admit that the pulsation of the child's heart and arteries, after its full extrusion into the world, and especially after severance of the umbilical cord, is a good evidence of life. Certainly the heart does not beat nor the pulse throb in a dead child; and there is no alternative between a dead child and a living one. Again, there can be no pulsations in the funis of a dead child; we all know that one of the surest signs of death in a child during parturition is the cessation of the pulsations of the cord. Furthermore, the redness of the lips and the healthy (not livid) appearance of the body, together with the rounded condition of the thorax, were highly suggestive of a feeble, though imperceptible, respiration.

The only attempt on the part of the plaintiffs to rebut this testimony was by alleging that this (admitted) life in the child was merely the remains of its intra-uterine life,—“a prolongation of its foetal life,”—extending its influence beyond the period when the child was separated from its mother, and galvanizing, as it were, what was in reality a lifeless mass of flesh and bones! This latter doctrine we hold to be untenable. The child was either alive or dead at its birth. Confessedly it was not born dead. No one would presume to bury an infant with its heart and arteries beating, and with a natural appearance of its lips and skin, even though it did not visibly breathe. Such a “prolongation” of life was, by the plaintiff's counsel, likened to the *momentum* imparted to a piece of machinery and retained for a while after the impelling power had been withdrawn. Here the motion might, in truth, be said to be merely the “remnant” of the antecedent power, and one that must of necessity soon come to a stop. But there is this immense difference between the two cases, which, at first sight, might seem so analogous: the machinery is but dead matter, subject merely to the laws of inertia; whilst the infant is endowed with a living organism capable of maintaining its own existence, provided it be furnished with the conditions of life. This

idea is further sustained by the well-known fact that many infants born apparently dead, and remaining for some time in this state, do actually revive and continue to live. I admit that in a very important sense its extra-uterine life was a "prolongation" of its foetal life, but precisely in the same way as it is in all our bodies. Certainly there is no *new* life imparted to a child after it is born. The principle of life mysteriously contained in the vivified germ is the same life continued on in the matured man, only developed. The life of the oak of a century's growth is essentially the same life that evidenced itself in the first swelling of the acorn beneath the soil. All we contend for is *life*,—not the amount or quantity of life, but the fact of life; and this latter, we think, was abundantly established by the evidence.

To discuss metaphysical subtleties on the subject of life before a court and jury, and to propound learned theories on the difference between intra- and extra-uterine life, in cases of this kind, may suit the purposes of ingenious counsel, but only serves to befog and confuse the plain common-sense jurymen. Besides, the rulings of the courts, both in England and in this country, have settled the question, in deciding that respiration (or crying) on the part of the new-born child is not required to establish the proof of a live birth, provided there are other evidences. Undoubtedly, the best physiological test of life is the pulsation of the heart. It is a more satisfactory proof than respiration, inasmuch as, in ordinary cases, life terminates in the heart, and not in the lungs or brain, since the heart is found to be beating some time after all evidences of breathing have ceased. The well-known experiments of Sir B. Brodie on animals also confirm this assertion. We do not pronounce a dying man to be *dead*, however feeble or inaudible his respiration may be, so long as we can feel or hear the throbbings of his heart; certainly we would hardly think it right to entomb such a person. And what is true of the man in this regard may be equally affirmed of the new-born infant.

This Delaware case may be regarded as a leading case in this country, and the finding of the jury (which was for the defendant) may be considered as establishing an important precedent in cases of a similar character. These cases, I may remark, are not of frequent occurrence; only a few have been reported in the English courts, and I can find but a single authenticated one in the law reports of the different States of our own country: that of *Garwood vs. Garwood*, which was tried in California in 1865. (Wharton and Stillé's *Med. Jurisp.*, 1873, vol. ii. p. 1083, *note*.)

In this latter case there were several circumstances in which it closely resembled the one in question: thus, the labor was protracted; the child did not breathe after it was born, but the umbilical cord and the heart beat for about fifteen minutes after extrusion from the mother; and the heart continued to pulsate two or three minutes after the severance of the cord. Besides, there were muscular movements of the hands and feet immediately after delivery.

In one of the English cases (*Fish vs. Palmer*) the court took the very extreme view that a mere twitching or tremulous motion of the lips of the child on its being put into warm water (and lasting but for a few moments) was sufficient to establish a live birth; and this without any observed pulsations in the heart or in the umbilical cord, or any sign of respiration. It seems to me that this is stretching the doctrine rather too far, inasmuch as the very slight contractions of the mouth that were noticed might be accounted for from the muscular irritability that had not yet been lost, but which, as is well known, continues for some time after death, and usually until cadaveric rigidity sets in. This *irritability* is believed to be an inherent property of the muscular tissue, and so long as it continues it may be excited by any external stimulus, such as cold, heat, electricity, etc., producing muscular contractions. But this sort of motion is a very different thing from the active movement of the blood in the heart and the umbilical vessels, produced by the regular rhythmic contractions of the child's heart, and kept up for half an hour after the complete extrusion of the child into the world.

Another English case (*Brock vs. Kelly*, *Taylor's Med. Jurisp.*, Am. ed., 1873, p. 625) came before Vice-Chancellor Stuart in 1861, and his decision confirms the views above expressed. Here "there was slight pulsation in the cord after separation from the mother, showing a feeble but independent circulation; there was no other indication of breathing than an arched state of the chest." In this case Dr. Tyler Smith considered that the beating of the umbilical cord "was a physiological proof that the child in question was not born dead;" whilst Drs. Lee and Ramsbotham, on the other side, testified that "nothing less than breathing could, in their judgment, establish the fact of a live birth." According to them, a child must breathe before it can be said to possess independent life. The vice-chancellor decided that proof of breathing was not necessary, and held that the pulsations of the cord, observed after birth, afforded sufficient legal evidence of a live birth.

That the above decision was based on sound physiological reasons is further shown by a case reported by Dr. Seale (*Am. Journ. Med. Sci.*, July, 1870, p. 278). He induced labor in a woman by means of ergot at about the seventh month of uterogestation. "A large child was born, after some difficulty, but it did not make the slightest effort to breathe; there was distinct pulsation in the cord." Was this child living, or dead? According to Drs. Ramsbotham and Lee, it was not alive. But the result proved the fallacy of such an opinion; for on subjecting the child to the action of hot and cold water, etc., "violent spasmodic contraction of the diaphragm took place, which continued for five minutes. The cord was now severed, and a little blood was allowed to escape from the foetal end; the tongue, which had fallen back, was drawn forward; a sudden spurt of a drachm of blood flowed when the constriction was relieved, and the child began to breathe very feebly, and so continued to breathe at long intervals. The heart beat very

feebly; the pupils widely dilated, and did not respond to light. This condition lasted one hour, when the child ceased breathing; the death being undoubtedly caused by compression of the brain."

I think, then, that the above-mentioned cases sufficiently sustain the position that respiration is *not* necessary to establish a live birth. As M. Bouchut justly remarks, "Apparent death succeeding to birth, and characterized by the presence of a beating of the heart and an absence of respiration, is *only a diseased condition* of the new-born child (*atelectasis*), and whether it is cured of this or dies, it is living, although it has not breathed." (*Gaz. des Hôp.*, 1855, No. 124.)

In the California case above alluded to, the opinion of the judge, as expressed in an able charge, was "that in the case in question it should be held that the beating of the heart was spontaneous, and that the child was born alive."

ON THE CAUSE AND PREVENTION OF TYPHOID FEVER IN SCHOOLS.

BY JOHN L. LECONTE, M.D.,

Late Medical Inspector U.S.A.

IN the beginning of January, 1875, I was requested to inspect St. Mary's Hall, Burlington, N.J. (a justly renowned school for the education of young ladies), in order to ascertain the cause of an outbreak of typhoid disease which had occurred some weeks before.

The cause, as is usual in such cases, was easily discovered, and the means for its removal and for the prevention of its recurrence readily determined. The suggestions which I made have been fully carried out by the trustees, and I in consequence gave a certificate stating that the necessary sanitary improvements had been made, and that there was no danger of a recurrence of typhoid disease.

These facts having come to the knowledge of several friends who are interested in sanitary science, I have been requested by them to prepare a short account of the causes which led to the development of the disease, and the results of the measures adopted for its suppression.

By the kind permission of the Board of Trustees of the school, I am now authorized to do this, and I hope that the lesson conveyed by these very simple observations will not be lost upon other institutions which are liable to similar misfortunes.

At the time that the hall was built, the water-supply was obtained from two cisterns, constructed of heavy wooden curbs, lined with brick and coated with cement. They were floored with timber, and descended below the level of subterranean drainage, by which spring-water would enter. In order to place the floor properly, a hole was cut in each to prevent the pressure of the spring-water. After the timber floor was fixed permanently, these holes were plugged, the plugs rising above the masonry bottom of the cistern. The water-supply was thus made to depend entirely upon the river; and had these arrangements continued without change I am

confident that no typhoid disease would have occurred.

A year later, without the knowledge of the authorities of the school, the plugs at the bottom of the cisterns were removed. This was a capital error, but would, perhaps, have been insignificant in its results had it not been supplemented by a second, the pernicious effects of which recently manifested themselves. A year or eighteen months afterwards (1871), privy-vaults were dug outside of the building for the reception of the excreta, which up to that time were received in boxes and removed every few days.

One of these privy-vaults was most inconsiderately placed about eight or twelve feet from the water-cisterns, which, as is mentioned above, had been opened to the influence of subterranean drainage. This privy vault seems to have been constructed with all the care usually exercised in the building of such receptacles,—bottom and sides nine-inch brick, laid in cement, heavily and carefully covered with cement, and arched over above.

The result was naturally what any student of sanitary science would have predicted. After a certain lapse of time (in this instance three years) the soil around the privy-vault became poisoned with the effluvia and infiltrations, and the water-supply in the cisterns thus became contaminated.

Having thus ascertained the cause of the disease, the remedy was, of course, evident, and of easy application. I was glad to find that it had been already recommended by the physicians of the establishment, Drs. Pugh and Gauntt, who, with admirable judgment, had, on the 18th of December, 1874, advised the disuse of the cisterns. It is a significant fact, as showing the correctness of my view that the contiguity of the privy-vault to the cisterns was the *sole cause* of the disease, that ten days after the water had been, by the advice of the physicians, drawn directly from the river, the last case of typhoid fever occurred, and since that time (28th of December) the school has been quite free from all similar disease.

One or two interesting facts were developed during my examination, which are worthy of mention. Although numerous cases of typhoid occurred among the girls, and a smaller proportion among the teachers, *not a single one* of the servants was affected. On inquiring of the latter whether they drank water, the reply was that they used only tea and coffee, and almost never drank between meals. The girls, on the contrary, like all children, are frequently thirsty, and drink often at intermediate hours of the day. The water consumed by the servants was, therefore, boiled, by which process the molecular activity of the putrescent matter was checked, and its power as a zymos was destroyed. No more admirable instance of the efficacy of this simple remedy for the purification of contaminated water can be found.

I asked the Rev. E. K. Smith, D.D., the principal of the school, what had been the fate of those pupils who did not use tea, coffee, or milk, but drank water exclusively. He told me that, after careful inquiry at the different tables in the refec-

tory, he ascertained that of seven absolute water-drinkers six had been attacked with typhoid.

In conclusion, I would invite the attention of my colleagues in the medical profession, and the governing authorities of schools, both public and private, to the ease with which all similar outbreaks of disease may be prevented, or, as in the present instance, speedily removed, by seeking scientific advice.

The following recommendations, if adopted, would, in most cases, prove effective.

1. Before the plans of the building are fully matured, let an expert in sanitary studies be employed to give directions to the architect in all that relates to ventilation, drainage, and water-supply.

2. After the building is completed, no alterations should be made affecting these three essentials of good hygienic condition, without the suggestion of a practised sanitarian.

3. There should be stated inspections, say twice a year, of each institution by some sanitarian of acknowledged merit, who, after close examination and the correction of any defect, would give a certificate to be published in the circular or announcement of the school.

4. On the outbreak of any zymotic disease in the institution, the advice of a sanitarian expert should at once be obtained, in order that means may be taken for its restriction, suppression, and prevention.

I may be permitted to add that at the last visit I made to St. Mary's Hall I found the sanitary condition perfect; and I cannot too highly commend the liberal manner in which the trustees have carried out the suggestions contained in my report, thus insuring, in my opinion, the health of the scholars confided to their care.

TRANSLATIONS.

CASE OF HYPERHIDROSIS UNILATERALIS.—Dr. Pokroffsky reports (*Berlin. Klin. Wochen.*, No. 13, 1875) the following case, which presented itself recently at Prof. Botkin's clinic in St. Petersburg. The patient, a man, presented the following appearances whenever he began to eat. The right side of the face, the greater part of the forehead, a part of the region about the shoulder, and the entire neighborhood of the temple, the ear, a little strip behind the ear, and the upper part of the neck on the right side, became decidedly red and covered with profuse perspiration. This collected gradually in large drops, and if not wiped away would run down over the body. The right half of the breast, the right arm and leg, were, during eating, somewhat warmer and more moist than the same parts on the left side. During the perspiration the right temporal artery became prominent, and pulsated markedly. Pulsation was noticeable also on the inner surface of the cheek. The pupils contracted equally; there was slight asymmetry of the face and tongue; the right eyelid could not be raised quite as high as the left.

During eating the temperature rose 0.2° to 0.4° , centigrade, in the right armpit, and other variations showed themselves later. Irritation of the sympathetic by the induced current during the patient's quiescence produced no effect similar to that brought on by eating;

but if the patient began to eat while the stream was passing, the usual symptoms were observed. Faradization of the cervical sympathetic during eating caused rapid diminution of the redness, and cooling of this side. Various investigations showed an apparently normal condition of the nervous system in general. However, electro-sensibility of the right cheek was diminished. The hearing, which was imperfect, was worse on the right side. Examination of the abdominal organs showed enlargement of the liver and spleen.

The increased secretion of sweat dated back to a fever from which the patient suffered in 1844, and which was accompanied by parotitis of the right side. X.

A MASCULINE MAIDEN.—An individual twenty years of age, who had always been regarded as a girl, and whose social status was that of the sex, discovered his mistaken identity at the age of eighteen. For two years he kept his secret, but, wishing to marry, he was of course obliged to change his social position.

The examination which he was obliged to undergo resulted in developing the following appearances as to the sexual organs. The scrotum, divided in the middle, contained both testicles, and on the left a scrotal hernia. When the penis was erect it was invisible while the thighs were closed, but when these were opened it could be seen pointing backwards. This resulted from the fact that the prepuce was closely attached to the scrotum. It lay in the raphé of the scrotum, not like a protuberance from the latter, but embedded in it, and, in fact, in such a manner that the frænulum was fastened to the skin of the scrotal juncture and to that of the perineum. The normal and erectile glans was quite free. The individual in question admitted having twice completed coitus.—*Centralblatt*, No. 16, 1875.

X.

VARIOUS METHODS OF TREATING WOUNDS.—The *Centralblatt für Chirurgie*, April 24, contains abstracts of papers on this subject by various writers, whose views are essentially as follows:

Dr. Ollier (*Comptes-Rendus*, tom. lxxx., 1875) recommends dressings of cotton with immovable occlusion. He says that although, when the wadding is removed, quantities of vibrios and other low organisms are discovered in the discharges, yet no evil comes of this.

The same pus, however, injected into the cellular tissue of a dog brought about gangrenous phlegmons. This shows how tolerant the surface of the wound becomes to the presence of this pus. Should daily removal and cleansing of the wound be practised, some fine granulations must almost inevitably become denuded, and an absorbing surface for the pus be made.

This explains the rise of temperature which follows each renewal of the dressing when this is frequently carried out. On the other hand, if the immovable and occlusive wadding bandage be retained in position until it has to be removed on account of the accumulation of purulent matter, the temperature of the patient will fall after the dressing is changed. Ollier has had remarkable success with the immobile and occluded dressings, and believes them the most appropriate in severe wounds, etc., and also that erysipelas is not so frequently met with.

Marc Sée (*Rev. de Thérap.*, 1875, No. 2) uses irrigation by means of weak alcohol. Wounds treated in this way take on new action, and, although proud flesh is apt to show itself, laudable pus makes its appearance, and the wound thus treated rapidly assumes a healthy granulation, and tends towards rapid recovery.

Nussbaum (*Aertzl. Intelligenzblatt*, 1875, No. 5) gives statistics from the surgical clinic at Munich, in support of Lister's method of treating wounds. Its figures certainly show a marked falling off of mortality subsequent to the use of salicylic acid. X.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, MAY 29, 1875.

EDITORIAL.

CONTRIBUTORS—PLEASE TAKE NOTICE.

IT may seem a matter of very trifling importance what cognomen is applied to a plant, animal, man, or paper. The old saw, it is true, affirms that a rose will smell as sweet with any other name; but in spite of this there was good sound sense, though not much worldly wisdom, in the brain of the young American who, seizing his nursing-bottle in one hand and the family carpet-bag in the other, indignantly left the house because his father and mother had finally settled upon Obadiah as a suitable title for him—their cherished first-born.

There really is much in a name,—much it may be that attracts, much it may be that repels; and because medical authors seem so often devoid of principle in their choice of titles we propose to call attention to the subject to-day.

In a novel or an article for a popular magazine, not only the title but even the very names of the characters play no small part in the achievement of success or in the shipwreck of failure. Any one conversant with Dickens's works knows the infinite appropriateness of the names of those personages whom his imagination has called into being. Uriah Heep "coming out strong" under difficulties is inconceivable, whilst for Mark Tapley to have taken upon himself the character of Bill Sykes would have been a violation of all the proprieties. Since the death of Mr. Dickens it has been discovered that he always selected his names with much care and thought, often rejecting many until he got the right

one. The first lesson we would like writers of medical papers to learn would be that the names of their papers should be selected with care and thought.

In a popular magazine article, if it be possible, a name should always be chosen of such character as to excite curiosity. From Victor Hugo's "L'Homme qui rit," to Dr. Mitchell's "Wear and Tear," this principle has underlain the choice of all successful titles.

A medical journal is read, in theory at least, for knowledge. Approaching with an insatiable appetite for this valuable commodity, its reader asks no condiment to whet his ardor, but only desires to be shown at once where is the morsel his soul craves. Hence the principle that the title of a medical article *should express as briefly but as plainly as possible the essence of the paper.*

When we started this editorial we expected to nurture it to full maturity; but just at this point the postman brought us the following article from Dr. Billings, of the Army Medical Library; and, as the lesser should always give way to the greater, we place here his article as received.

"ON TITLES OF ARTICLES IN MEDICAL JOURNALS."

"A medical journal is a library on a small scale, and, like it, is usually a combination of a treasure-house and rubbish-heap.

"One object which the editor and the librarian should keep in view is the separation of the refuse from the jewels as far as possible, and for this purpose much depends upon the system of labels or titles. If it were fully appreciated how much of the practical value of journal articles, and the probability that the latter will be referred to by those seeking information, depends upon the title, it seems to me that more care would be taken by both authors and editors to see that the subject of the paper is properly described by its heading.

"It is very seldom that the physician will find, in examining the last number of his medical journal, any article that bears directly upon his work then on hand. It may be months or years before he will need to refer to it, and the possibility of his doing so will depend much on the index, which last depends upon the titles.

"For about ninety per cent. of journal and transaction articles the title is the most important part, as showing what one should avoid reading; and if a good descriptive title cannot be made, there is reason for suspecting that the paper is not worth printing.

"What information is given by such titles as the following: 'A Remarkable Case,' 'Singular Malformation,' 'Paralysis from Injury,' 'The Fever of 1852,' 'The Case of Mary Dobbs,' 'The Trial of Dr. Jones,' etc.?

"How much reference will probably be made to papers headed 'Pathological Observations,' 'Therapeutical Memoranda,' 'Notes of a Practitioner,' etc.?

"Again, titles are often incorrect. 'A Case of Gastrotomy,' for instance, may be a case of Cæsarean section, colotomy, laparotomy, or true gastrotomy.

"For the sake of bibliographers, librarians, and the writers and teachers of the future, I would request that each contributor to the great storehouse of medical literature shall label his packages properly and distinctly."

UNIVERSITY OF MICHIGAN.

THE Legislature of Michigan has just passed the following bill:

"SECTION I.—The people of the State of Michigan enact: The Board of Regents of the University of Michigan are hereby authorized to establish a homœopathic medical college as a branch or department of said University, which shall be located at Ann Arbor.

"SECTION II.—The Treasurer of the State of Michigan shall on the first day of January, 1876, pay out of the general fund, to the order of the Treasurer of the Board of Regents, the sum of six thousand dollars, and the same amount on the first day of January of each year thereafter, which moneys shall be used by said regents exclusively for the benefit of said department."

If the Regents had some time since requested of the Legislature sufficient money to put the medical department upon the same basis as Harvard, would not their request have been granted?

CORRESPONDENCE.

NEW YORK, May 14, 1875.

THE venerable Alonzo Clark still continues his weekly clinics at the College of Physicians and Surgeons. These are maintained with great regularity throughout the year, with the exception of a couple of months or so in the summer, and always attract quite a large number of students.

What strikes a casual visitor most at first is the imperturbable gravity of the old Professor. This characteristic was well shown, for instance, at the clinic on Thursday, when a lad presented himself complaining of a pain in his stomach, which he afterwards, however, concluded was in his chest.

The boy was not sufficiently intelligent to give a satisfactory account of himself, and, after he had been put through a course of cross-questioning, in which his answers were contradictory enough to have driven a lawyer to distraction, but which never for a moment ruffled Dr. Clark's dignified serenity, a careful physical examination of the abdominal region was made. At its conclusion, the learned Professor announced, with the same air of importance as though he had discovered the presence of cancer of the pylorus or a perityphilitic abscess, that unless the patient was suffering from intes-

tinal colic he was at a loss how to interpret his symptoms. During all this time not the faintest suspicion of a smile was ever discoverable upon his placid features.

There were no cases of special interest brought before the class on this occasion. The first after that just spoken of was one of dyspepsia, in an artisan, characterized by great pain and uneasiness, free eructations and occasional bilious vomiting after eating, and a constant bad taste in the mouth. As he complained of excessive palpitation during these attacks of pain, an examination of the heart was made, when it was found to be enlarged; the præcordial dulness extended laterally an inch farther than normal, and an aortic murmur was also detected. There was no history of rheumatism. The patient was put upon ten grains of pepsin by starch and five drops of the strong nitromuriatic acid in as many tablespoonfuls of water, immediately after meals. No treatment was suggested for the cardiac trouble, except that he should observe great care in his habits of life.

The last case presented was one of spasmodic asthma. The patient was a cigar-maker by trade, and had suffered from this affection for eleven years. The attacks usually came on in the night, towards morning, and often lasted twenty-four hours. Their average frequency was about once a week. The last one had occurred early that morning, but had been less severe than usual. The urgent dyspnœa had now passed away, but the characteristic whistling, unaccompanied by mixed râles, could still be plainly heard all over the chest. In this case it was especially prominent in inspiration. Prof. Clark stated that asthma might be due either to emphysema of the lungs, or enlargement of the right side of the heart. When emphysema was present, it could usually be detected on percussion, in one or both subscapular regions. In this case there was no cardiac hypertrophy, and neither could emphysema be very clearly made out, though the vesicular resonance on the right side, behind, was rather greater than that on the left. No mention was made of spasmodic asthma as a purely neuropathic affection, without necessarily involving any appreciable lesion. He regarded the painful dyspnœa in asthma as due to two causes, congestion of the mucous membrane, and spasmodic contraction of the smaller bronchial tubes.

The treatment resolved itself into two parts, that of the paroxysm, and that of the halix. For the former he considered the inhalation of the smoke of stramonium-leaves, either in the form of cigarettes or by a pipe, the most efficient remedy. If a pipe was used, it was better for the patient to blow the smoke first into a hat, and then breathe it in, in order to avoid the swallowing of acrid oils. The inhalation of the fumes of nitre-paper, ether, and chloroform were also employed by some. Another class of agents afforded relief by producing nausea, and of these lobelia was most in repute. Dr. Clark did not allude at all to the use of nitrite of amyl in this affection. The only remedy for the halix to be considered, he said, was the iodide of potassium,

and this was an exceedingly uncertain one. When this failed absolutely, the only chance for a cure was in a change of locality; and it was a remarkable fact that there seemed to be some place or other where every asthmatic could be entirely free from his troublesome attacks. Colorado has some reputation in this respect just now; but, though it may suit some, there are vast numbers of others upon whom its climate would have no effect whatever. Salter had found that benefit was often derived from a residence in the smokiest part of smoky London; and, acting on this suggestion, Dr. Clark had sent some of his patients to Pittsburg. But he found it would not do: there was too much sulphur in the air there. He then related an instance of both the members of a business firm being affected with asthma. As their manufactory, however, was in Newburgh and their sales-rooms in New York, and as one gentleman never suffered from its attacks while in the former place, and the other in the latter, they were thus enabled to attend very satisfactorily to the management of their business. The only rule was for a patient to go from place to place until he found a locality where he was free from the disease.

At his clinic at Bellevue Hospital, on Saturday, April 24, Prof. Jacobi again brought before the class the case which was reported in our last letter as one of *scleroderma*, and said that after a more careful study of its history and clinical features he had arrived at the conclusion that it ought more correctly to be considered a case of true atrophy of the skin. The disease commenced about the chest, where there was still some discoloration in *plaques*, but new adipose tissue was forming there, and there was now decided improvement in this part. The treatment had consisted of cod-liver oil and Fowler's solution. He ascertained that the younger child was not suffering from the same affection, as stated by some of the family.

A great deal of talk, and not a little indignation, have been excited here by a recent action of the Board of Managers of the Presbyterian Hospital. At this institution the appointments of visiting physicians and surgeons are for one year; but it has always been understood that each of the staff would be annually re-elected during "good behavior." Now, however, the Board have suddenly dropped four of the physicians (one of whom at the time was prostrated by a dangerous attack of typhoid fever), and elected four others, generally acknowledged to be less competent for the position. Some feeling is expressed against the latter gentlemen for accepting the appointments under the circumstances. As is so often the case, the *deus ex machina* in this matter proves to be a woman. The only offence of the physicians removed, so far as we have been able to ascertain, is that they were not altogether acceptable to her serene highness the matron of the hospital, who, it seems, is permitted to ride rough-shod over both doctors and directors.

There appears to be something wrong about the management of the Presbyterian Hospital; for, with elegant and commodious new buildings, constructed on the

best modern sanitary principles and in one of the finest situations in the whole city, the institution has never been a popular one. While it must have ample capacity for between one and two hundred patients, the average number, we have been told, is only *twenty-four*.

Some hospitals and asylums in the government of which the ladies have a controlling influence seem as bad as church choirs for "unpleasantnesses."

The annual report (just issued) of an institution in the administration of whose affairs there has never been any lack of harmony, and whose direction is mainly, as it ought to be, in the hands of medical men, now lies before us. It is that of the New York Free Dispensary for Sick Children, the only institution of its kind in the city, and which, though still in its infancy, is already acknowledged to be one of the important charities of the metropolis. It was started four years ago, by Dr. B. F. Dawson, who is still its President, and to whom its present usefulness and prosperity are almost entirely due. During the first year of its existence 1989 patients were treated at the Dispensary; during the second, 2672; during the third, 3323, and in the fourth, 4858. This continuous increase shows that the institution has ministered to a real need in the community, and that greater and greater demands have been made upon it as it has become more widely known. Its financial affairs have always been managed with ability and economy. When the dispensary was first proposed, \$465 was collected among a few friends to start it with. Now the treasurer's report shows a balance of over \$6000, notwithstanding the annual expenses have increased to nearly \$2000. All the funds for its support with the exception of \$300* have been contributed by the generosity of friends, and an annual ball at Delmonico's, which is looked forward to with delight by the fairest of the descendants of the Knickerbockers, is now one of its principal sources of revenue. No salaries are paid by the institution, not even a druggist's; the prescriptions being put up, at a reduced rate, by a reliable apothecary in the vicinity. It is proposed, as soon as practicable, to establish a hospital in connection with the dispensary, as there is now only one real child's hospital in the city,—St. Mary's,—an institution of the Episcopal Church, whose capacity is but twenty-six beds.

A short time ago, a certain Dr. Lambert read a paper before the Liberal Club on the "Special Articles of Food adapted to the Nutrition of the Brain, and the Methods of Cooking them." Preparatory to this he invited some of his friends to a banquet, which is thus taken off by one of the daily papers: "Last evening a party of gentlemen ate a 'brainial' dinner at Jones' restaurant, in Broadway, their host being Dr. T. S. Lambert. Mr. James Parton and about twenty others more or less well known sat around the board and nourished their brains to a somewhat alarming extent. The waiters grinned from ear to ear when they served the food, for not one of them had ever dreamed of a din-

* Appropriated by the Legislature.

ner beginning with toasted crackers and cheese and ending with boiled custard and buttermilk. The 'brainial' qualities of toasted cheese have long been known to scientific men, and nearly all the members of the Liberal Club are passionately fond of boiled custard, which, as is well known, contains over ninety per cent. of phosphorus, and will readily burn if rum be poured over it. Dr. Lambert lectures to-night on 'Brain-Building,' and it was to raise the intellects of his audience to a high place that he gave this exhibition of encephalotropophagy, or brainial food. Such a dinner will do occasionally, but is dangerous if too often indulged in. The human brain is about eighty per cent. water, and if it be stuffed with the sublimations of cheese, oysters, codfish, tripe, calves' brains, oat groats, and boiled custard, it becomes a powerful battery, a perilous magazine, liable at any moment to explode, to the great detriment of its owner and the surprise of bystanders. By the time the sixth course, which consisted of stewed tripe and green peas, was reached, the excitement became fearfully intense, and with the calves' brains the feast became almost an orgie. The forehead of the Pantarch grew four inches higher with the great pressure from within upon the convolutions, but happily the ganglion where oatmeal becomes universology was not affected in any marked degree. The parietal bones of a great Comptist separated, and the coronal suture widened quite perceptibly. Around the brow of a mighty Spiritualist there was a marked nimbus, where the escaping phosphorus ignited upon coming in contact with the oxygen of the air. It was singular in the extreme to watch the oatmeal rising to the brain; to see the subtle poison of the boiled custard turn a man into a demon of ratiocination; and as the fiery buttermilk mounted to the intellect and hurled the reason reeling from its throne, the beholder was fain to acknowledge that the gods are just, and of our pleasant vices make instruments to plague us."

Two suits for alleged malpractice have just been decided in a way that shows a very fair amount of discernment on the part of the juries, as juries go. The first has been argued for several days past in the Supreme Court, before Judge Van Brunt, and was that of Edward P. Doyle against the New York Eye and Ear Infirmary and Dr. Richard Derby, one of our well-known ophthalmic surgeons, for \$100,000 damages for the loss of his eyesight. The patient was suffering from purulent ophthalmia, and left the institution while still under treatment, and before sight was destroyed. The jury were out but ten minutes, and rendered a verdict for the defendants. The other suit was brought against Augustus McCollom, a person who has been practising dentistry without any diploma. It appears from the evidence that the plaintiff, while having some teeth filled by him, received considerable injury by his unskilfulness. Alveolar abscess ensued, and this resulted in tetanus, which nearly proved fatal. In this case, also, the jury was absent only about ten minutes, and then returned a verdict for the plaintiff; damages, \$435.

PERTINAX.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, MARCH 11, 1875.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

Lungs from a case of emphysema.

DR. F. P. HENRY presented the specimens, and read the following history:

"Virginia S., æt. 24, was admitted to the Episcopal Hospital on September 27, 1874. Her illness, which has lasted about a year, began with a chill, followed by pain in the left side, cough, and swelling of feet and legs. She suffered from *chills and fever* during the entire summer.

"On admission, she presented the following symptoms and signs: Decided emaciation, dull expression of countenance, pallor, and profuse perspiration night and day. Sputa copious, tenacious and yellowish, and emit a faint, disagreeable, sickening odor. Flatness over the entire left thorax up to the supra-scapular region, and to a corresponding line in front; above that point, dulness. Respiratory sounds absent in the region of flatness. In the region of dulness there is a high-pitched, almost musical sound, attending expiration; this sound is prolonged, and is heard much less distinctly in front. The inspiratory sound in the region of dulness is bronchial. At the right apex there is a blowing expiratory sound, and dulness on percussion. Below, the resonance and respiration are normal.

"The heart's apex-beat is under the right nipple.

"The decubitus is constantly upon the left side; any attempt to lie upon the right side invariably brings on an attack of coughing, which does not cease until the original position is resumed.

"There is too great an amount of œdema upon the left side to make it possible to decide whether there is any bulging of the intercostal spaces. In the early part of October, measurement showed the left semi-circumference of the thorax to be an inch greater than the right.

"The treatment of the case was at first purely medical, and consisted of measures to promote absorption of the effused fluid, the nature of which at that time could not be determined with certainty.

"On November 13, the fluid having in the mean time increased in quantity, I requested the attending surgeon, Dr. Packard, to perform paracentesis. This was done at the eighth interspace, and three-fourths of a pint of pus was withdrawn by means of the aspirator. I was surprised at the result, as it was evident there was a much greater amount of fluid in the pleural sac. The position of the heart remained the same, and no expansion of the lung could be detected. Nevertheless, there was a decided improvement in the general condition of the patient after the operation, and her respiration was free. This improvement was of not more than a week's duration.

"On December 19 I tapped in the seventh interspace, and removed four pints of pus with the aspirator. The improvement was this time somewhat more permanent, but about January 1 the unfavorable symptoms began to return. The dyspnœa became more urgent, the cough more troublesome, and the sweating more profuse, in spite of large doses of belladonna, which had previously held it in check. At this date the patient was taking thirty ounces of milk-punch (one-third whisky) and sixteen grains of quinia in the twenty-four hours.

"January 3, 1875, morning. — Temperature, 98½°; pulse, 100; respiration, 28.

"Evening.—Temperature, 99°; pulse, 98; respiration, 26.

"January 4, morning.—Temperature, 101½°; pulse, 108; respiration, 40.

"This sudden increase in pulse, respiration, and temperature may be attributed to agitation of mind at the prospect of another operation. On this day Dr. Ashhurst, the attending surgeon, tapped in the eighth interspace, removed five quarts of thick, greenish-yellow pus through a trocar, and introduced an india-rubber drainage-tube.

"Evening.—Temperature, 100¾°; pulse, 116; respiration, 44. Since the operation about a pint and a half of pus has drained away. The air which passes in and out of the pleural sac, with a loud rattling noise, at each respiration, renders it impossible to determine whether the lung has expanded to any extent.

"January 5.—Feels better. A.M., pulse, 94; temperature, 98°; respiration, 27. P.M., has some nausea, and diarrhoea. Pus continues to drain away at about the rate of a pint in twenty-four hours.

"Pulse, 120; temperature, 102½°; respiration, 38.

"January 6.—Passed a restless night, and is very weak. Milk-punch disagreeing, plain milk and brandy and egg are substituted. Pleural cavity was washed out, first with tepid water, afterwards with a dilute solution of liq. iodin. comp. (3i to Oiss), and, lastly, with tepid water. Pulse, 104; temperature, 101°; respiration, 48. About 3 P.M. there was vomiting of a greenish fluid, and soon after the patient passed into a state of collapse, and died about 4 o'clock.

"The *autopsy* was made twenty hours after death, by the resident physician, Dr. Merrill.

"Liver somewhat enlarged, and fatty. Intestines, mesenteric glands, kidneys, and spleen normal. The heart was pushed far over to the right side, where it had contracted adhesions. Some recent lymph was observed upon the visceral layer of the right pleura, and some fluid in the corresponding cavity. A few caseous nodules at the right apex.

"The left lung was compressed into a firm oblong mass, not much larger than the fist, and lay in the upper and back part of the cavity, being closely bound down to the vertebræ. The pleura was greatly thickened, and the lung was covered with a layer of inspissated pus.

"There are two depressions in the lung-tissue which at first sight might be regarded as communications between the pleural sac and the bronchi, but water could not be forced through them by injection from the left bronchus. They appear to be abortive attempts at perforation of the lung. There are two firm and large circular bands of adhesion between the two pleural layers."

Dr. JOHN GUITÉRAS asked whether there were any physical signs in this case to indicate the falling of the lung back against the spinal column.

Dr. HENRY replied that vocal resonance was not increased, but there was blowing breathing above the spinous process of the scapula.

Dr. GUITÉRAS said he asked the question because a man had recently died at the Philadelphia Hospital who was thought to have pneumonia because there was posteriorly such very distinct bronchial breathing, vocal resonance, and vocal fremitus. After death he was found to have pleurisy, and the lung was closely pressed against the vertebræ. It is true the examination was somewhat careless, being only posterior, because the sounds there heard were thought to be so characteristic; but the mistake was complete.

Dr. ALLEN asked what was the duration of the case.

Dr. GUITÉRAS replied that the man came into the drunkards' ward, and died in a few days after admission.

Dr. ALLEN asked whether the fluid was purulent.

Dr. GUITÉRAS said it was not.

Ovarian tumor.

Dr. HENRY also presented a specimen of ovarian tumor, removed post mortem, but, he thought, none the less interesting pathologically on that account. The patient from whom it was obtained was admitted to the Episcopal Hospital on February 2. Her abdomen was enormously distended. She had been tapped about two weeks before admission, for the eighteenth or nineteenth time, when, according to her statement, four pailfuls of fluid were removed. Fluctuation was easily obtained all over the abdomen, which was evenly distended.

She first noticed a swelling in the hypogastric region at the time of the menopause, about three years ago. She was tapped February 18, and two and a half bucketfuls of a fluid of the consistence and color of syrup of acacia were removed. Before the tapping the circumference of the abdomen was sixty-one inches. After a quantity of the fluid had drained away, a large tumor was felt in the right side of the abdomen, extending from the ribs to the iliac region. Her attention was called to it, and she then said that she had discovered it some months before, after one of her numerous tappings, and had called the attention of her physician to it, whereupon he pronounced it to be the liver.

The tapping only reduced the woman's girth six inches, but was followed by great relief.

Having decided the case to be one of ovarian tumor, which opinion was confirmed by the attending surgeon, Dr. Forbes, arrangements were made to have the woman transferred to the surgical side of the house. On February 25 she was informed of the proposed change, at which she was greatly agitated, and declared that she could never survive an operation. At this time she was in her usual state of health, but she grew worse towards the afternoon, and died the next morning about ten minutes before my visit to the hospital. Dr. Merrill, the resident physician, said there was some dyspnoea preceding death.

At the post-mortem examination it was only possible to examine the abdomen, and that only because it was impossible to get the body in the coffin without reducing its size. The large cyst was adherent to the anterior wall of the abdomen. There was some recent lymph upon the intestines, and the tumor felt during life was found free on the right side. The heart was not examined, and so the cause of death cannot be pronounced upon with certainty. My opinion is that it may have been from heart-clot of gradual formation. The heart-sounds were feeble, but there was no valvular murmur, and the urine did not contain albumen.

Rupture of the aorta.

Dr. W. G. PORTER presented the specimen, and read the following history:

"On the 11th of March I was requested to make a post-mortem examination of the body of a colored man, about 40 years of age, who had suddenly died while at work two days before. He was an unusually strong and well-developed man, who had followed the sea until about eight years ago, when, while in the harbor of Galveston, Texas, he was severely injured by a fall from the mast-head to the deck. He was laid up in the hospital at that place for several weeks, but the nature of his injuries it was impossible to ascertain at the time of the post-mortem. After the accident he had been working in this city, most of the time being employed as a 'longshoreman'; for the last few weeks, however, he had been driving a dray. On Thursday evening last he visited a neighboring drug-store, complaining of a stitch in the right side, for which he procured a warming-plaster. On Friday he worked as usual; on Saturday, while at work, he suddenly went and sat down on

a box, his head fell forward on his breast, and before anything could be done for him he was dead.

Post-mortem examination.—The body was that of an unusually muscular man. On opening the pericardium it was found that it was filled with clotted and fluid blood, and on careful examination an extremely minute opening in the aorta was found on the anterior surface of that vessel immediately above the base of the heart. No atheromatous deposits were found in the aorta, and the other organs were all healthy, with the exception of a slight pleurisy on the right side.

Dr. GUITÉRAS asked whether there was any history of syphilis or rheumatism.

Dr. PORTER replied that he had never attended the man previously, and knew nothing about him, but that he had attended his children for some time, and had not met with any symptoms of syphilis in them.

Dr. GUITÉRAS said that there had evidently been some chronic disease going on here. The aorta is very much thickened, and the heart is probably fatty. There had been a thinning out of the walls at the point of ulceration until the adventitia had bulged out and finally ruptured. This process was also indicated by the ragged edges of the inner opening. This case he thought corroborated the opinion he had expressed with regard to a similar case which he had presented two weeks ago, in which rupture of the heart was suspected to have occurred, but where he thought there was really a rupture of the aorta, the heart having been accidentally wounded during the autopsy.

The specimen was referred to the Committee on Morbid Growths, which reported, March 25, 1875, as follows:

"The atheromatous process in the aorta, presented by Dr. Porter, has ulcerated through the inner and middle coats of the vessel, immediately behind the point of insertion of one of the semilunar leaflets, and there formed a small aneurismal pouch in the adventitia which extends like a diverticulum into the pericardial cavity. The walls of this aneurism are unusually thin, and microscopically nothing but connective-tissue fibres were detected. Upon opening the sac, a small clot was found in its interior. The hemorrhagic effusion found in the pericardium no doubt ensued through the rupture of this small aneurism."

SELECTIONS.

UNILATERAL SWEATING.—Experimental pathology has long pointed to an affection of the sympathetic system as the probable cause of unilateral sweating, since Bernard found that when the sympathetic was divided on one side in horses, there was sweating, as well as dilatation of the blood-vessels, on the affected half of the body. The supposition has lately been confirmed by the post-mortem examination in a case of this affection which is briefly related by Ebstein in the current number of *Virchow's Archiv*. The subject was an æmic man sixty years of age, and the unilateral sweating affected the left side of the head and trunk and the left arm. The affected parts were not reddened, nor was there any alteration in the pupil. At first the sweating only attended some severe anginal seizures, but afterwards it occurred on any considerable exertion, even in walking up and down a room. Examination of the sympathetic ganglia, hardened in Müller's fluid and alcohol, showed that those of the left side, especially the lower cervical ganglion, presented brown dots and lines visible to the naked eye, and consisting of cavities filled with blood-corpuscles and lined by a distinct endothelium. The walls were thick, and contained many spindle-shaped nuclei. The

vessels were dilated, sometimes varicose. The ganglion-cells were pigmented; on some the nucleus was quite concealed by dark-colored granules. On the right side the nerve-cells presented a similar appearance, but there were none of the cavities, and the vessels were much less dilated.

Ebstein believes that transient interference with the function of the ganglion-cells may have resulted from occasional temporary over-distention of the dilated vessels with blood, consequent on hindrances to the escape of the venous blood. To such transient paralysis of the ganglion-cells he ascribes the hemidrosis. Analogous changes in the ganglia have been found by Lubinoff in several instances of various disorders, as puerperal fever, etc., but they were much slighter than in the case detailed by Ebstein.—*London Lancet*.

ACUTE MYELITIS.—Dr. Guérin-Roze (*La France Méd.*) mentioned a case of this disease at the Société Méd. des Hôpitaux, of which the following are the particulars: A man aged 46 came into the Beaujon Hospital on July 31, 1874. This man suddenly, without warning, had the evening before felt his legs give way under him, and fell down. At the morning visit paralysis of the lower limbs was observed, but he could move his legs. The arms were intact, and sensibility was normal.

The night of the 31st July was passed by the patient without sleep; the arms were affected, and at the morning visit there was paralysis of the muscles, with slight febrile condition. Pulse 88; temperature 37.5°. Dr. Guérin-Roze diagnosed acute generalized myelitis—cause unknown. However, it seemed that the patient had complained some time before of headache, like strokes of a hammer, and three months previously such an attack had got well by means of a purge; another attack was treated unsuccessfully. There was also retention of urine, which was acid, without odor, and sensation was intact.

On the 2d August and following days the pulse was quicker, palsy persisted, but the intellect was clear; some moist râles were heard in the chest. On the 8th there were symptoms of asphyxia, with cadaveric rigidity, and the patient succumbed on the 18th, after twelve days' illness. At the post-mortem examination congestion of the brain was noted; the sinuses, filled with blood, presented a sand-like aspect; in the spinal cavity there were seven chalky and irregular plates, three in front and four behind; there was a dirty serosity, with softening of the anterior segment of the dorsal region and of the inferior segment of the lumbar region.—*Medical Press and Circular*.

CIRCUMCISION.—Dr. De Saint-Germain (*La France Méd.*, April 10, 1875) recently delivered a clinical lecture at the Hôpital des Enfants Malades on Circumcision. The lecturer said that dorsal incision of the prepuce could not be considered as a true circumcision. The discovery of the operation is very ancient, and 1900 years before our epoch we find Abraham practising it. It had from the commencement all the characters of a religious rite, and not of mere hygienic precaution. Herodotus says the Jews borrowed it from the Egyptians; but this is not clear. In general, infants have a long prepuce, and the skin and the mucous membrane are prolonged beyond the gland, forming a sort of little cylinder more or less wrinkled and irregular. This is the ordinary character, and when it disappears the author thought that masturbation existed. Under the influence of this fatal habit the glans is frequently uncovered and exposed to the air and the friction of the clothes; it becomes wrinkled, and the prepuce covers it more exactly. Marjolin attached great importance to this symptom.

The indications for the operation are very numerous.

First, we have imperforation of the prepuce, which is a rather frequent malformation; in two or three days the newly-born infant has not passed urine. There is developed at the extremity of the penis a tumor of some size, tense, fluctuating, a true urinary cyst, and we must hasten to incise the prepuce or to practise circumcision to give passage to the urine.

Circumcision may be of some utility as a preventive means or a curative method in masturbation. In this point of view it is of no use after the age of ten; but at the age of five or six we may obtain a cure. As a general rule, masturbation is a moral disease, against which we must most generally employ moral treatment.

Phimosis is a serious obstacle to fecundation. Hutchinson has much insisted on the remarkable immunity from syphilis or soft chancre found among Jews. Perhaps he is right, for the gland, when constantly uncovered, is flattened, retracted, and indurated, and is no longer covered by mucous membrane, but by a kind of skin.

M. Tarnot, in 1865, published a very interesting study on the practice of circumcision in Algeria among the Jews and Arabs. It is practised among the former eight days after birth.

The Arabs look on circumcision only as a hygienic practice, and await the age of twelve or thirteen before employing it. The operator ties a ligature on the prepuce in front of the gland, and cuts off the part of the prepuce beyond it with a razor.

We may add that MM. Gillet and Grandmont are much in favor of the application of the galvanic cautery to the operation of phimosis.—*Medical Press and Circular*.

CÆSAREAN SECTION FOR CONTRACTED PELVIS (Dr. E. Martin).—The labor began at 3 P.M. At 10 P.M., the pains being good, with the anterior lip swollen, and the fœtal heart-sounds being still distinct, Cæsarean section was performed. An incision 11 or 12 centimetres (about 4.7 or 4.8 inches) long was made in the linea alba, extending to the left of the navel for about 0.8 inch above it. Hemorrhage was slight, but became profuse on the uterine incision striking the margin of the placenta. An incision about 11 centimetres (4.6 inches) long was made in the uterine walls, purposely more towards the fundus than the cervix. The child was extracted breech foremost, in order to prevent any laceration of the uterus towards the cervix; a small rent did take place at the fundal end of the incision. The fœtus was removed without any difficulty. The child weighed 3180 grammes (7 lbs.), and measured 49 centimetres (about 19½ inches). After rapid removal of the placenta, the hemorrhage from the uterine wound, which was rather profuse, was easily stopped by means of fourteen catgut sutures. The abdominal cavity was most carefully cleaned out with prepared sponges. The abdominal walls were closed with iron-wire sutures, which were passed through the peritoneum; short strips of adhesive plaster were applied between them. A compress soaked in a solution of carbolic acid (1 per cent.) was laid on the wound, and over this cold water, but later on ice-cold applications. The progress of the puerperium was not a particularly disturbed one. The sutures were in part removed on the twelfth and in part on the fourteenth day. She got up on the seventeenth day and left the hospital on the twentieth; when seen three weeks afterwards, she was perfectly well.—*London Medical Record*; from *Berlin. Klin. Woch.*, No. 51, 1875.

WILL AND CHARTERIS ON CHLORAL AS AN ANTIDOTE TO STRYCHNIA.—The *British Medical Journal* for January 23 contained a report by Dr. Hughes Bennett, on behalf of the committee appointed by the British Medical Association to investigate the antago-

nism of medicines, in which it was shown that in the lower animals chloral acts as an antidote to poisonous doses of strychnia. Dr. Ogilvie Will, of Aberdeen, records, in the *Edinburgh Medical Journal* for April, an opportunity which he lately had of demonstrating that this fact is true also of the human subject.

A druggist's apprentice, aged eighteen, swallowed, with suicidal intent, a quantity of pure strychnia. The lad thought he had taken five or six grains,—"certainly not less than four,"—but the exact amount could not be ascertained, as he had emptied it out of a bottle at haphazard; but from the rapidity with which the symptoms appeared—only a few minutes after swallowing the poison—and from their severity, it was evident that the dose must have been a large one.

Medical assistance was quickly obtained; and when Dr. Will saw the patient, an emetic had been given and other attempts made to induce vomiting, but without success; violent attacks of convulsions had already commenced, recurring at intervals of about five minutes; often several fits would occur in succession with only a minute or two between each. Dr. Will at once sent for some chloral; but whilst this was being procured the fits rapidly increased in severity and in duration, and when it arrived the patient appeared actually moribund,—as if he could not live many minutes. Thirty grains of chloral were at once administered by the mouth, and "in a very few minutes the good effects began to manifest themselves; the intervals between the spasms became longer, and the spasms themselves lessened in severity." Another thirty grains were then injected under the skin, and almost immediately afterwards a further change for the better was observed. Later in the afternoon, however,—the poison having been taken a little before 2 P.M.,—the fits again began to increase gradually in frequency and intensity; accordingly, at 5 P.M. thirty grains of chloral were again given by the mouth, and at 6.30 fifteen grains were injected hypodermically. After this the fits subsided; occasional twitchings continued for a few hours; these ceased during the night, and next day the patient was convalescent.

Dr. Charteris, of Glasgow, reports a very similar case in the *Lancet* for April 10. In this instance the patient, a very strong, healthy man, aged thirty-nine, deliberately swallowed the contents of two sixpenny packets of "Gibson's Vermin-Killer" mixed with whisky and ginger-beer, each packet containing fully two grains of strychnia. The poison was taken at about 11.30 A.M., soon after a very substantial meal of ham and eggs, etc., and the symptoms came on very slowly and gradually. It was not till 3.30 P.M. that he was brought to the Royal Infirmary; violent attacks of convulsions were then occurring about every ten minutes. The stomach-pump was used, but the fits continued to increase in severity and frequency until 4.50, when ten grains of chloral were given, and the dose was cautiously repeated at intervals of about twenty minutes. There was little change until forty grains had been given, but then the improvement was rapid and marked; the spasms subsided into mere muscular twitches, and the patient became calmer. The chloral was now given at gradually longer intervals; about 3 A.M. the spasms ceased altogether, and the patient complained only of aching and soreness in the muscles. He recovered completely in three or four days.—J. W. LANGMORE, M.D., in the *London Medical Record*.

SANGUINARIA (*American Journal of Pharmacy*, May, 1875).—Mr. Lewis C. Hopp has found that the supposed alkaloid puccina is nothing more than sanguinarina with some resin and coloring-matter persistently adhering to it, and that sanguinarinic acid is a mixture of citric and malic acids.

GLEANINGS FROM OUR EXCHANGES.

ADDISON'S DISEASE (*The Lancet*, April 17, 1875).—Dr. E. Headlam Greenhow believes that the following deductions may be safely drawn from the data which we possess, although they are undoubtedly imperfect.

The occurrence of Addison's disease takes place almost exclusively among persons employed in active manual labor.

The mortality caused by it is pretty equally distributed over the laborious period of life, and to that period it is almost entirely confined.

The disease is comparatively much more frequent among persons of the male sex, whose employments naturally comprise the heaviest kinds of labor.

And, lastly, a preponderating number of the cases which occur in persons of the male sex are found among those classes of laborers whose occupations are likely to expose them to injury from accident or over-exertion.

The facts thus brought out cannot fail to suggest obvious inferences as to the probability that in many of these cases more or less temporary causes of local inflammation may have existed; and Dr. Greenhow is inclined to believe the origin of Addison's disease in many unexplained cases to be due to traumatic causes, although probably favored in its development by certain constitutional proclivities.

The diagnosis is founded upon the constitutional symptoms, aided, in a large majority of cases, by the presence of more or less of the peculiar change of color in the skin. It is not always unattended with difficulty, but to those who have any practical acquaintance with the disease it is not more doubtful than the diagnosis of many other chronic diseases. The prognosis is invariably grave as regards the ultimate result, though it is impossible to say to what extent life may be prolonged under favorable circumstances. Rest and scrupulous avoidance of bodily and mental excitement, or any other causes of nervous exhaustion, form the essential parts of the therapeutic management of all such cases; whilst the diet and medical treatment must be carefully adapted to the inevitably varying phases of the disease.

BALSAM COPAIBÆ (*The Practitioner*, April, 1875).—Mr. A. R. Hall briefly records some cases in which he has found the use of copaiba to be productive of great benefit. In a case of ophthalmia occurring in a syphilitic patient and in which the whole anterior chamber was filled with pus, two drachms of copaiba were given in mucilage three times daily, with the result of destroying the pain, causing the absorption of the pus, and ultimately curing the patient. Mr. Hall gives it in all cases of iritis and scleritis in large doses, and asserts that it speedily causes the pain and inflammation to disappear. In thirty cases of purulent ophthalmia occurring in children he simply painted the lower eyelids, upper part of the cheeks, and temples with the pure balsam, and they all got well quickly without any damage to the eyes. In threatened mammary abscess, dysentery, chronic rheumatism, and even in indolent leg-ulcers, he has found great benefit to follow its administration.

INJURIES TO THE HEAD (*Medical Times and Gazette*, February 27, 1875).—Mr. Jonathan Hutchinson points out that the danger of laceration of the scalp, especially if it be accompanied by detachment of the pericranium, consists in the occurrence of suppuration between the bone and the internal periosteum, to be followed in its turn by inflammation of the arachnoid membrane; and secondly in the choking of the gangrenous veins of the diploe of the dying fragment with coagula and the pro-

ducts of inflammation, which may extend to the sinuses and cause pyæmia. Some of the most typical cases of pyæmia are induced by the death of a very small area of bone. In cases in which the propriety of primary trephining is debated, the surgeon may put wholly aside any fears as to increased risk of pyæmia after that procedure, and may adopt it or not, as the other circumstances of the case may indicate.

TRAUMATIC POPLITEAL ARTERIO-VEIN ANEURISM—LIGATURE OF THE ARTERY AND VEIN—RECOVERY (*The Lancet*, April 24, 1875).—Mr. Thomas Annandale reports the case of a boy, æt. 10, who received a wound in the popliteal space, which resulted in an irregular pulsatile swelling, the size of an infant's head, and which was diagnosed as an aneurism of the popliteal artery. It was decided to treat it by laying open the sac and tying the artery above and below the wound. A tourniquet was applied to the femoral, and a limited opening was made into the sac to admit of the separation with the finger of any adherent clots. The sac was then opened freely by a wound about five inches in length, and all the blood and clot in it sponged out. There was not very much clot, the contents consisting principally of fluid arterial blood. By this proceeding two openings were clearly exposed at the bottom of the sac. These openings were parallel to each other at a distance of about an eighth of an inch in the longitudinal direction of the limb. They were both about a quarter of an inch in length, and had the appearance of slits with little gaping of the edges. A probe passed into each opening determined the fact that one communicated with the canal of the popliteal artery, and the other with that of the popliteal vein. The canals of both vessels were pervious as far as the probe would pass above and below the wounds. The sac of the aneurism was well formed, circumscribed, and white and smooth on its inner surface. The popliteal artery, being carefully cleared by dissection for a short distance, was ligatured above and below the wound with prepared catgut; and the popliteal vein, being cleared in the same way, was also ligatured above and below the wound with the same material. The tourniquet and elastic ligature were now removed, and a small artery and vein which bled, in the region of the wounded vessel, were tied also with catgut. A drainage-tube was then introduced into the cavity, and antiseptic muslin was applied in the usual way, after the edges of the wound had been stitched together. The whole operation was performed under the antiseptic spray.

The case resulted in a perfect cure, without any complication.

Mr. Annandale considers that this case has practically demonstrated that both artery and vein may be successfully ligatured, and he confidently recommends the adoption of this plan of operation, which has never before been practised in this class of cases.

The advantages of this plan are, in his opinion, (1) certain closure of the openings of communication in both artery and vein; (2) absence of any risk from venous hemorrhage or absorption in connection with the wounded vein; (3) its practicability in the large majority of cases; (4) its easy performance without much dissection.

A NEW METHOD OF ARRESTING HEMORRHAGE (*The Medical Record*, May 1, 1875).—In a recent clinical lecture, Dr. Weber, after considering the general anatomy of the arterial system, the mechanism of the spontaneous closure of divided vessels, and some of the more evident objections to the employment of ligatures, torsion, acupuncture, etc., continued as follows:

We should have a process of treating the divided

vessel which would simply assist nature, not supplant her, by mechanically-acting principles. The failure of nature to arrest hemorrhage spontaneously in larger-sized arteries is unquestionably due to the fact that they do not possess, for cogent physical reasons, sufficient muscular and circularly-arranged fibres to bring about the contraction and diminution of the short axis of the vessel, and to effect longitudinal pleating, which we believe important both for the evolution of the fibrinoplastic agency and the security of the clot when formed. It does not seem probable that, other things being equal, the greater force of the blood, on account of the larger size of its column, should be the only reason why the spontaneous arrest cannot take place in a larger vessel.

We know that the muscular tissue of the middle coat, the chief contractile material, is not commensurate with the size of the vessel; that, in fact, as remarked before, it positively diminishes with the size of the vessel. There must be a reason for this; it cannot be accidental. It must find its explanation in the physical necessities of the circulation of the blood in large vessels.

Now, if this be correct, and if the want of sufficient contractile force is the cause of the non-arrest of bleeding, can we not rectify matters by simply doubling or trebling the amount of the circularly-acting tissue, by turning the end of the vessel inside out, as we would turn up the cuff of a sleeve? By so doing we would obtain double or treble the amount of contractile force, and also furnish an equivalent for retraction.

Carrying out this notion, Dr. Weber obtained an instrument by which he could fix the vessel at the time of turning over its coats, and which he describes as the *fixateur à gaine* of M. Luër of Paris. He made a number of experiments on dogs, with satisfactory results, and found that he could prevent the vessel from becoming straight again after the reflection had been made, by simply notching its extremity at each end of a transverse diameter. The notch was made through the two walls,—the main wall and the reflected,—and, commencing at the point of reflection, extended about two lines in a longitudinal direction.

Owing to the contraction of the circular fibres after division, a wedge-shaped gap was formed at each notch, so that the circumference of the vessel at the edge of reflection was increased. This caused the reflected piece to appear to surround the end of the vessel more closely,—in fact, to constrict it.

If this does not prove sufficient to retain the reflection *in situ*, he introduces immediately behind the point of reflection a little delicate peg, made of the end of a No. 12 English sewing-needle; and should this fail to arrest the bleeding instantaneously, he applies digital compression for a short time to the end of the artery. He has now tried this plan on the anterior and posterior tibial, the brachial and the femoral arteries, and with complete success. He has found that very small arteries can be everted as easily and promptly as larger ones; and believes that the method is justifiable and practicable in a large number of surgical operations.

CHLORIDE OF ZINC (*Medical Press and Circular*, April 7, 1875).—Mr. Lister has found chloride of zinc to have the remarkable property, among all antiseptics that he has tried, that a single application of it to a recent wound in a solution of the strength of 40 grains to the ounce of water, although it produces no visible slough, yet prevents the occurrence of putrefaction on the cut surfaces for days together, in spite of the action of the septic material; and if the discharges have opportunity to flow freely away, as after the removal of a tumor of one of the jaws or a portion of the tongue, there may be absolutely no odor from first to last, the divided textures being thus guarded from the bad effects of the

putrefaction during the dangerous period before they have been covered by the protecting layer of granulations.

MISCELLANY.

DRESS AS A CAUSE OF PELVIC DEFORMITY.—When the body is erect, says Dr. Aveling, in a discussion of this subject in the *Obstetrical Journal* for January, the influence of dress is of sufficient importance to demand careful attention. Attitude depends upon clothing more than is generally supposed. The stooping position, which has been referred to as injurious, is often produced by the peculiar feminine vestmental arrangements at present in fashion. The greater part of the burden of a woman's clothing hangs from the posterior part of her body. All the folds of her skirts are carefully disposed behind, and the swaying influence of their weight here is much increased by the leverage power granted them by the numerous ingenious devices adopted for insuring their projection backwards from the body. As the balance can only be maintained by inclining the body in the opposite direction to that in which it is drawn, it must necessarily be bent forward to counterpoise this retroverting influence. High heels also throw the body out of its proper balance, producing stooping, relaxation of the abdominal walls, and debased pelvic inclination. But dress, in its strictest sense, has still another potent way of causing mischief,—namely, by its weight when suspended from the waist; a weight not inconsiderable in itself, but rendered of much consequence by its persistent action. The bands, from which the garments that women wear hang, are chiefly supported by the abdominal walls and the viscera beneath them. Ultimately, therefore, they must compress the pelvic organs and cause their downward displacement. As a rule, all vestments should be carried by the shoulders. Long robes falling from them and girded at the waist are the least harmful, if not the most beautiful garments a woman can wear. If, however, it be absolutely necessary that her dress should be divided into two portions at the waist, let her by all means adopt some method of suspending the lower half from the shoulders. Braces of a very simple and inexpensive kind, having safety-hooks, which may be passed through the bands of the skirts, are now easily obtainable, and their general adoption is much to be desired. The position of the waistband must also be considered, for whether it should be high or low is a point of much importance. The fashion of short-waisted dresses is far more healthy. Long waists involve abdominal compression by stays, and that closer contact of bands with the walls of the abdomen which enables the downward dragging weight of skirts to exercise its influence most injuriously. The natural position of a woman's waist is neither high nor low, but in that part of her body which happens to be the smallest in circumference. If fashion would only allow this to be the proper place for the waistband, we should not, as now, have the constriction of stays and the

gravitation of garments conspiring in the production of prolapse and its concomitant disorders.—*London Medical Record*.

VARIETY OF TINTS.—As an illustration of the limitless number of combinations which the three primary colors are capable of, it may be interesting to know that in the Gobelin tapestry manufacture twenty-eight thousand distinct shadings of yarn are employed, each one distinguishable by the practised eye.—*Journal of Applied Science*.

SLATE FOR ENGRAVERS.—As a matter of interest to any desiring illustrations, the discovery is worth noting that plates of polished slate may be used as substitutes for boxwood in engraving. It is stated that such engraved plates will furnish 100,000 impressions without loss of detail, and are not affected by oil or water. One drawback which they possess is that they are readily scratched, an objection from which wood is almost free.

STRATEGY VERSUS STRENGTH.—According to the *Cincinnati Medical News*, a Spanish physician, J. Fuentes, resorted to the following expedient in a forceps case. He says, "It was during the night, at an hour very unseasonable to call for assistance of a colleague; after fruitless attempts, my strength was entirely exhausted. I was all in a perspiration, and inexpressibly fatigued, when a practical idea occurred to my mind. I remembered how wire-makers pull the copper for wire. I procured at once a strong belt, which I fixed around my waist, and in it I hooked the free handles of the forceps that had been properly applied; then, holding my knees against the bedside and pulling methodically together with my waist and arms, I succeeded easily in bringing out the fœtus alive and free from injury."

POISONING BY NITRATE OF SILVER.—A case is reported in the *Brighton Guardian* in which a man hastily took a piece of lunar caustic, thinking it to be an anti-bilious pill. Soon after, he felt a burning in the throat. The patient said he felt the caustic in the right side of the throat, but his physician, Mr. Hart, searched for it with his finger, and could feel nothing. Two or three hours after, Mr. Hart was sent for, and found great difficulty of breathing, for which he performed an operation and carried on artificial respiration. But the man died. At the post-mortem, the stomach was found congested. "On examining the throat, at the back of the tongue he found a large black patch in the fold of the mucous membrane, where the poison had lodged. The passage into the lungs was completely blocked up, and the throat much swollen. Deceased died from suffocation." A similar case to the above, in which croup was caused by a bit of caustic dropping into the windpipe, is recorded by Dr. Albers, of Bremen, and mentioned by Christison.

WASHING out of the stomach, and the aspiration of liquids secreted by it, is more and more practised in Germany, since Kussmaul highly praised this method. Dr. Schliep uses it in nearly all affections of the stomach, especially in chronic gastritis, with or without dilata-

tion. The cure of chronic catarrh, according to his account in the *Deutsche Klinik*, vol. xvi., would require but a limited number of applications. In simple catarrh, five would suffice, on an average. He uses this method even in the dyspepsia of consumptive patients. In dilatation of the stomach, he empties that organ with the pump every day. He performs the washing out even in cancer; he uses pure water, or adds bicarbonate of soda to the water, if the liquids be very acid; or permanganate of potash, if the liquids show signs of fermentation; carbolic acid, when they contain vegetable parasites; boracic acid, as a disinfectant; and tincture of myrrh, in atonic dyspepsia with abundant secretion of mucus.—*Boston Medical and Surgical Journal*.

CURIOUS EPITAPH.—In the Jews' Burial-Ground at Bethnal Green is the following:

Mrs.

S earch England or the universe around,
A doctress so compleat cannot be found;
M edicines prepared from herbs remove each ill,
P erfect great cures and proclaim her skill.
S ome hundreds her assistance frequent claim,
O ften recorded by the trump of fame.
N ow, reader, see if you can tell her name.

—*Medical Press and Circular*.

SPECIFIC GRAVITY OF CHOLESTERINE.—When crystallized cholesteroline is dropped upon the surface or diffused in a finely-divided state through water, it floats upon the surface. From this it has been concluded that this body is less dense than water.

M. Mehu, in a communication to the *Société de Pharmacie*, proves by a series of ingenious experiments that cholesteroline is in reality heavier than water,—having a density, according to his determinations, of 1.747.

The floating of cholesteroline upon water is due to the adherence of minute air-bubbles, which not only attach themselves to the sides of the crystals, but are found between the lamellar plates of which the crystals are themselves composed.—*The Laboratory*.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MAY 18, 1875, TO MAY 24, 1875, INCLUSIVE.

HAMMOND, J. F., SURGEON.—To report to the Commanding General, Military Division of the Atlantic, for duty as Attending Surgeon, relieving Surgeon Bill. S. O. 92, A. G. O., May 17, 1875.

BYRNE, C. C., SURGEON.—Assigned to duty as Post-Surgeon at Fort A. Lincoln, D. T. S. O. 88, Department of Dakota, May 18, 1875.

WEEDS, J. F., SURGEON.—When relieved by Surgeon Byrne, to comply with S. O. 75, c. s., War Department. S. O. 88, Department of Dakota, May 18, 1875.

WOLVERTON, W. D., ASSISTANT-SURGEON.—Assigned to duty at Fort Abercrombie, D. T. S. O. 87, Department of Dakota, May 15, 1875.

KNICKERBOCKER, B., ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Fort Colville, W. T. S. O. 58, Department of the Columbia, May 7, 1875.

BROWN, J. M., ASSISTANT-SURGEON.—Leave of absence extended twenty-three days. S. O. 97, Military Division of the Atlantic, May 17, 1875.

BROOKE, JOHN, ASSISTANT-SURGEON.—Relieved from duty in Department of the Columbia, to proceed to Philadelphia, Pennsylvania, and, upon arrival, report by letter to the Surgeon-General. S. O. 92, c. s., A. G. O.

STEINMETZ, WILLIAM R., ASSISTANT-SURGEON.—Relieved from temporary duty at Fort McHenry, Maryland, to report to the President of the Army Medical Board, New York City, for examination for promotion, and, upon its completion, to the Commanding General, Department of the Missouri, for assignment to duty. S. O. 92, c. s., A. G. O.

SATURDAY, JUNE 5, 1875.

ORIGINAL LECTURES.

CLINICAL LECTURE ON LUPUS ERYTHEMATOSUS.

BY LOUIS A. DUHRING, M.D.,

Clinical Professor of Diseases of the Skin in the University of Pennsylvania.

Delivered May 18, 1875.

Reported by ARTHUR VAN HARLINGEN, M.D., Chief of the Skin Clinic.

GENTLEMEN,—The patient whom we have before us, and whose case shall form the subject of my lecture to-day, presents an affection of such interest that I shall devote the greater part of the hour to its consideration. It is one which, although not very uncommon, does not often present itself developed to the extent to which we have it here. Her history is as follows:

She is a married woman, 26 years of age, with light-brown hair. The affection for which she seeks relief first made its appearance fourteen months ago, as a roundish patch, situated on one side of the nose. From this point it began to spread over the face on the same side, and, some time after, attacked the other side of the face, extending under the eyes in the form of a semicircle. Afterwards it appeared successively on the forehead above the nose, on the side of the chin, and on the right side of the head behind the ear. The disease has never shown itself in any other part of the body. The patient is of large frame, stout, well nourished, and enjoys average general health; she has gained flesh since the appearance of the skin-trouble. Her appetite is good, bowels somewhat constipated, menstrual discharge regular but scanty. She has always been subject to cold hands and feet, even in summer-time. For the last three years she has suffered from occasional headaches, occurring, perhaps, every few days or once a week. For some years past she has been troubled with seborrhœa of the scalp, and she has this trouble at present. Before the present disease broke out, the skin was remarkably free of eruption of any kind. About five years ago she had a slight attack of rheumatism, which has not been repeated. Although the disease of the face has been better and worse from time to time, yet it has never shown any tendency to disappear; it is said to be spreading slowly now from week to week. So much for the history.

Proceeding to the examination of the eruption, we observe that it consists of numerous variously-shaped patches, mostly roundish, the size of a split pea and larger, many of which have coalesced and form patches of greater size. The cheeks are involved symmetrically, the area of disease on either side being perhaps the size of the palm, and extending from the lower eyelid almost to the ramus of the jaw. The nose is partially invaded; the bridge and the tip being especially attacked. The alæ of the nose are free, as well as the region about the mouth, chin, and the red part of the lips. Beneath the lower lip and around the chin there are

circular, isolated patches, from the size of a pea to that of a cherry. A similar patch may also be noticed back of the right ear; the lobes of the latter are free. The eyelids are partially invaded, the spaces between brow and lid being symmetrically occupied by elongated patches, which also extend around the inner canthi, close to the conjunctivæ. On the forehead you will notice two irregularly-shaped, linear patches, extending outwards from the nose half-way up towards the scalp.

The patches over the cheeks are purplish-red in color, and are covered with very fine, adherent, greenish-white and yellowish scales. The mouths of the sebaceous glands are everywhere open. The skin, moreover, has an inflammatory appearance, feels hot at times, and occasionally itches and burns very severely. The itching has been a more or less constant symptom, but has not manifested itself more of late than earlier in the history of the disease. The line of demarcation is everywhere well marked; the diseased patches, although but very little elevated, terminate abruptly against the sound skin. The isolated, circular patches, which are the most recent manifestations of the disease, also show a sharply-defined border, likewise but slightly raised. Our patient tells us that the patches vary considerably in color at different times, occasionally becoming quite purplish, at other times of a much paler hue. It should be remarked that she experiences no pain.

The course of the affection has been intermittent; it has increased by attacks taking place every few weeks, at which time the disease would spread considerably in a few days, and then remain quiescent during the interval.

Now, having heard this woman's history, and having made a careful examination of the appearances presented, let us leave the investigation of this individual case, and go into a consideration of the affection in general.

The affection before us is known under several different names: lupus erythematosus or erythematoses, seborrhœa congestiva, etc. Bielt, who first described it many years ago, gave it the title "*lupus qui détruit en surface*," in view of the fact that while the disease is a destructive one as regards the cutaneous tissues, its action is not deep like that of lupus vulgaris, but is confined to the upper layers of the skin. The name seborrhœa congestiva was originally given by Hebra, who regarded the seat of the disease to be in the sebaceous glands, but he afterwards modified his views on the subject of its pathology and abandoned this name for that by which the affection is now generally known, lupus erythematosus, erythematous lupus.

Lupus erythematosus is included under the class of "cellular new formations." Its usual seat is upon the face, where it most commonly shows itself first on the bridge of the nose, spreading out over the cheeks on either side, so as to form the appearance of a butterfly, a simile first noted by Hebra. A word as to color. It is variable, sometimes light, again dark; very often it is a beefy red, like inflammatory psoriasis.

The patches are always more or less covered, as we have seen, with scales, whitish, yellowish or greenish in color, and very adherent. The disease is invariably superficial in character; it never goes on to ulceration; there is never any moisture, and the appearance of a given patch is always the same from one month to another.

Lupus erythematosus is, as I have said, usually confined to the face, for which locality it has a strong preference, and particularly for the cheeks. It, however, does occur on the body. Occasionally we see it on the red portion of the lips, as in this photograph which I show you.

Lupus erythematosus is a disease of adult age; it never makes its appearance before puberty. In this respect it is quite different from lupus vulgaris, which is apt to make its appearance at an early age. This is an important point, for these diseases are often confounded.

The causes which produce the disease are obscure, but are at times the same as those which bring on ordinary seborrhœa, *e.g.* anæmia, chlorosis, and the like. The French have given the disease the name (among others) of *Scrofulide Érythémateuse*, but this often proves a misnomer: there is certainly no sign of scrofula in the case before us; our patient is a fine, hearty young woman, showing no sign of any constitutional taint whatsoever.

As regards diagnosis, the tissues involved, the shape and locality of the patches, the characteristic greenish, strongly-adherent scales, are all so peculiar that in most cases there can be but little difficulty.

There are, however, five diseases with which, under some circumstances, lupus erythematosus might be confounded. The first of these is lupus vulgaris. In this affection, however, we find papules and tubercles almost always present; neither of these are found in lupus erythematosus. The fact mentioned a little while ago, that our disease is one of adult life, while lupus vulgaris always begins in the young, may also be remembered. Both diseases are apt to attack the face, but the formation of tubercles which subsequently break down into ulceration would decide the matter. The brownish crusts found occasionally over the lupus vulgaris patch might be mistaken for the scales of lupus erythematosus, but a closer examination would show that in the first case we have *crusts* formed of dried pus, while in the other we have *epithelial scales*.

Secondly, we may sometimes mistake lupus erythematosus for psoriasis. The general appearance of the eruption before us is not unlike that of a patch of psoriasis, but we should hardly be likely to find the latter disease in one large area on the face, but rather in a number of smaller patches. Besides this, close examination of the scales would show a very decided difference. Those of psoriasis are friable, flat, superficial and easily picked off, while the scales of lupus erythematosus are exceedingly adherent, and when removed show villous projections consisting of the contents of sebaceous glands, with occasionally a cast of their lining membrane.

Thirdly, the disease before us resembles at first

glance certain forms of syphilis, but upon closer inspection we could hardly fail to exclude this. The history and course of the affection, moreover, would aid in deciding the matter.

Fourthly, we might confound lupus erythematosus with eczema, but, although a superficial glance might cause us to hesitate a moment, an examination would reveal the absence of the characteristic eczematous weeping and crusting; the glandular involvement would in addition be quite sufficient to distinguish them.

Fifthly, lupus erythematosus has occasionally been mistaken for *tinea circinata*. The history of the disease, however, would show that its course is far different from that pursued by ring-worm of the face. Microscopic examination of the scales would serve to dissipate any doubt.

Now, as to the pathology of the disease. It begins in the glands of the skin, chiefly the sebaceous glands. If you examine the case before us, you will notice that in certain places the sebaceous follicles are enlarged, plugged up with altered sebaceous matter, and covered by an adherent scale. Beyond the region of the disease itself, you may see sebaceous glands congested and swollen, which will in time become new centres of disease. The greenish color of the scales is in part due to their natural color, in part the result of admixture with dirt.

The disease-action begins by an infiltration or deposit of fine cells in the corium, and particularly about the sebaceous glands. They are minute, highly refractive, and roundish, not unlike granulation-cells. They are very persistent. Lupus erythematosus is a markedly inflammatory disease; itching and burning are frequently (though not always) observed. The extent of these symptoms is variable.

They are aggravated by different external causes. Our patient, for instance, notices that when she goes out into the open air, and particularly when her face is exposed to the wind, they are more severe. I have frequently observed the same fact in other cases. The course of the disease is uncertain; it suddenly spreads a few lines or more, and then stops for a time. It is during this rapid growth that the itching and burning are most violent.

As regards prognosis and treatment; cases of this disease are apt to prove exceedingly stubborn, yet differ greatly in this respect: one may get well quite rapidly, while the next will resist all treatment. Occasionally patients who are attacked in so severe a manner as in the case before us are carried off by some intercurrent disease, as erysipelas; this, however, is not common, nor is it explainable. I simply present it as a fact which has been noticed by several good observers (Hebra, Kaposi).

There is no specific treatment for lupus erythematosus; we must manage each case as may prove best for it. Among the internal remedies most likely to prove useful are cod-liver oil, arsenic, iron, and iodide of potassium, together with all those means ordinarily employed for the purpose of raising the tone of the system and improving nutrition.

As regards external remedies, stimulant and caustic applications, and particularly alkalies, are

most useful. Among the best of the latter is the ordinary *sapo viridis* or soft soap (containing about four per cent. of caustic potassa in excess). This may be rubbed into the diseased patches with the aid of a flannel rag, a little warm water being added from time to time. After the scales and débris are thoroughly cleaned away, the surface of the patch may be washed with pure water, dried, and some ointment, preferably the *unguentum hydrargyri*, applied, spread upon cloths of proper size and shape. These applications should be made twice daily. We may substitute the preparation known as "*spiritus saponis alkalinus*," a solution of *sapo viridis* in absolute alcohol, for the soap, and in some cases with advantage.

Instead of mercurial ointment, other preparations of a somewhat more stimulating nature may be employed. Among these the ointments of red iodide of mercury, sulphur, and iodide of sulphur, may be mentioned.

All these should be tried before having recourse to stronger applications; but when the milder forms of treatment have failed, the strong caustics may be employed. Solution of caustic potassa, one part to four or eight of water, may be advantageously applied with a small swab, rubbing the diseased surface, and quickly applying vinegar or dilute acetic acid to neutralize the alkali and prevent excessive caustic action. Of course, where there is a large patch, only a portion should be gone over at any one time; the eschar which forms may be dressed with water, or olive oil on lint. The cauterization may be repeated every week or so, until the whole diseased tissue has been destroyed. Of course this is a last resort, but it usually answers when everything else fails.

A strong solution of carbolic acid, or even the crystals themselves, may also be used. The application, however, is a very painful one, and the smarting lasts some hours.

In the case before us we shall begin by giving our patient the iodide of potassium in the dose of ten grains thrice daily, and shall, for the present, use no local treatment.

Finally, let me advise you to gain your patient's confidence before beginning any course of treatment. We shall tell this woman that the affection is a tedious one, may last a long time, months, or even years, and let her commence with a full appreciation of the necessity of patience. On the other hand, we shall make her understand the necessity of efficient and sustained treatment. *Lupus erythematosus* never, or at least very rarely, gets well spontaneously.

INSOLATION DURING PREGNANCY (*American Journal of Obstetrics*, May, 1875).—Dr. M. B. Wright reports a case in which during the three weeks preceding labor the temperature of the mother was greatly elevated, pulse 120 to 140, intense headache. These symptoms all disappeared within twenty hours after the delivery of a fetus two or three weeks in advance of full term, weighing about six pounds, and similarly overheated. The liquor amnii and placenta were also found to be much above their usual temperature. No definite cause for these peculiar phenomena was discovered.

ORIGINAL COMMUNICATIONS.

PHOTOGRAPHIC ENLARGEMENTS OF MICROSCOPIC OBJECTS.

BY CARL SEILER, M.D.,
Philadelphia.

Read before the Biological and Microscopical Section of the Academy of Natural Sciences, and recommended for publication in the Philadelphia Medical Times.

THE processes of different workers in microphotography, with all the minute details and description of the apparatus used, have repeatedly been published, so that I have to ask your indulgence for bringing again a new apparatus to your notice.

The first experiments I made in this direction were attended with very little success, which, however, did not discourage me. They were made with a complete microscope and camera,—that is to say, eye-piece and photographic objective were retained, while reflected sunlight was used for illumination. In continuing my experiments the objective of the camera and the eye-piece were found useless, and were discarded, and without them better negatives were obtained. The great objection was the motion which resulted from even the slightest tremor of the house, caused by passing wagons or by the walking of persons in rooms above or below. This motion and its consequences were removed to a great extent by discarding the body of the microscope, and by using the objective in connection with the camera, or, rather, a long wooden box. In this way the microscope and the camera were converted into one instrument. But two difficulties presented themselves in using this new form of apparatus,—viz., that of obtaining the picture on the ground glass in focus, and that of illumination of the object. The first was overcome by using a quarter portrait-tube, and putting in the place of the front combination a disk with a central opening, into which the objective was screwed, the back combination of the tube having been removed. Then by passing a resined cord over the mill-head of the tube I was enabled to bring the object in focus, being at some distance from it. This was done by pulling at the ends of the cord, and thus revolving the mill-head, which caused the approximation of the lens to the object. A stage was then constructed by extending an arm in front of the tube with a perforated plate at right angles to it, upon which the specimen was secured by clamps. For illumination, a large concave reflector was placed at some distance in front, and so bringing the light to a focus directly in front of the object.

This form of apparatus I did not find necessary to alter materially; all I did to improve it was to make the body of the camera of paper, and extensible, so that it can be lengthened to ten feet, and to add a movable stage, which, moved by long rods, enables me to bring any part of the object into the field. For the cord I substituted a rod and two friction-gear wheels, with which I can focus with considerable fineness. The main difficulty, however, was, and still is, the illumination; and it was only

after a long series of experiments that I could obtain tolerable results.

The first condition, at least for histological preparations, is that the light should be absolutely central. Even then the image on the ground glass will be a confused one, with bright lines and dark shadows, and single cells or blood-disks will show three and four outlines, the rays of light being bent in their course through the object. It has been recommended to interpose a piece of ground glass between the reflector and the object, in order to diffuse the light and so get rid of this difficulty. But I found that this does not answer the purpose, as it reduces the penetrating power of the objective, and also takes away the *crispness* of the picture, if I may use this expression. It does, however, flatten the field very considerably, and is of great advantage in vegetable and insect preparations, where the lines are comparatively coarse. Rendering the light monochromatic by means of a solution of ammonio-sulphate of copper contained in a glass cell obviates this trouble to a certain extent, and has also the advantage of bringing the chemical and the visual focus almost in the same plane, as well as of absorbing the heat-rays which would otherwise destroy the object. As this solution becomes turbid if the cell is not perfectly tight, and as it penetrates almost any substance, I had at first considerable difficulty in keeping the solution clear. I now use a cell made of glass in the following manner: a hole is ground into a one-fourth inch thick piece of plate-glass, extending to the margin, with a conical opening. Then two pieces of thin plate-glass are cemented on each side of the thick glass by means of a mixture of glue and molasses. In this way a circular cell is formed, with a funnel-shaped opening on the top, through which the solution may be introduced and then the opening closed by a tight-fitting cork. If now this monochromatic sunlight is concentrated by means of an achromatic condenser upon the object, the result on the ground glass is far better in every respect than without the condenser. It must, however, be used with caution, so as not to introduce too much light, as in that case it is impossible to give the sensitive plate the proper time of exposure.

The greatest advantage, however, I derived from introducing diaphragms into the condenser and objective, and also into the camera itself, in this way cutting off all superfluous light. As the German lenses, which I am compelled to use, do not allow the introduction of a stop between the front and back lenses, I fitted a cap with a small opening over the front lens, and another over the back lens. These stops increase the penetrating power of the objective considerably, and also make the picture appear on the ground glass almost as sharp and crisp as it is seen in the microscope itself.

It has also been recommended to take the focus on clear plate-glass with an eye-piece, because the surface of the ground glass is too rough to allow a slight difference in focus to be seen, while it is readily perceived in the negative. But focussing with the eye-piece is not only very tedious, but also more uncertain than even the roughest ground

glass; at least it has proved so in my hands. I use for a focussing-screen a piece of plate-glass which has been varnished on one side, and then rubbed with alcohol, which makes it slightly turbid,—not enough to prevent transparency, but sufficient to make the picture apparent.

It is as a matter of course most important that only the best preparations should be used, the quality of the objectives being of far less importance. Most of the specimens which I used, and of which I placed a few photographs on the table, I obtained through the kindness of Dr. J. G. Hunt. The preparation of the negatives and prints is the same as in ordinary photographic work, with the exception that the negative cannot be made strong enough by mere development with iron, and has therefore to be intensified in order to print well.

It is hardly necessary for me to say that the advantages, both for teachers and students, which may be derived from good photographs of microscopic objects, are very great, as drawings, no matter how well and faithfully executed, always can give only that which the artist or draughtsman has seen; and we all know how very deceptive appearances in the microscope sometimes are, so that even those who are perfectly familiar with the instrument and object are often misled,—how much more easily those who are not familiar with microscopy, and who are only occasionally required to make a drawing of what they see in the instrument!

Micro-photography, however, is as yet in its infancy, and the results obtained are by no means perfect; but they are encouraging, and I hope that by perseverance pictures may be obtained which will be equal to the one formed on the retina of the human eye.

THE MOLOCH OF TRADITION.

BY BENJAMIN LEE, A.M., M.D.

AT the meeting of the Philadelphia County Medical Society of February 11, 1874, I had the honor to present a paper entitled "The Practical Identity of True Croup and Diphtheria." I had first written "The *Essential* Identity," but changed it, thinking by softening a little the positiveness of its assertion to provoke less opposition in the minds of my hearers to the doctrine which I desired to maintain. I wish to preface this brief addendum to that paper (which subsequently appeared in this journal) with the statement that I consider the identity essential as well as practical, and practical because essential. My aim, then, was not so much to present my own views or to frame an argument in their support, as to show how great a weight of authority could be brought to bear on that side of the question from the contemporary writings of European physicians, especially Continental. I confess I was unprepared for the entire lack of concurrence with which the proposition was received. My heavy ordnance, borrowed for the occasion, produced no more impression on the Society than a carefully-mounted battery of pop-guns on an iron-clad. While there was no lack

of kindly commendation of the labor displayed in the preparation of the essay, it was evident that the theory broached was unanimously condemned as rank heresy. Even the accomplished author of the paper on "Tracheotomy in its Relations to Croup and Diphtheria," which followed soon after, on whom, as a man of advanced views, I supposed I could count as a second, showed himself still bound with the cords of dogmatic teaching, a firm believer in the purely sthenic inflammatory character of membranous croup.

For the sacrifice of what hecatombs of lives is this miserable word inflammation, or the misuse of it, responsible! And if we are now to have a revival of indiscriminate phlebotomy, how gory will be the altar of the Moloch of tradition! I have since had gratifying evidence, however, that certain practical hints which I threw out in regard to the early use of antizymotics and tonics, and the avoidance of all depressant measures at the outset of every case of acute faucial disease, before it has had time to differentiate itself, did not fall altogether dead. I simply wish now to call the attention of those who were kind enough to listen to or read the former somewhat lengthy article, to the fact that the ranks of those who maintain the specific character of true croup as simply a form of diphtheria have recently received two most powerful accessions in England.

From an article by Sir William Jenner, entitled "Clinical Lecture on Croup and the Diseases that resemble it" (*Lancet*, January 16, 1875), I make the following extracts, and I desire to say that they are in no sense garbled, but represent the opinions of the distinguished author as honestly and exactly as the entire article would do:

"Membranous inflammation of the larynx—inflammation, that is, attended by the presence of lymph on the surface of the mucous membrane of the larynx—is croup. This is a peculiar form of inflammation, as the presence of the lymph proves. . . . The inflammation is a so-called specific inflammation. . . . Diphtheria is an acute specific disease, attended by inflammation of the pharynx, having, as its result, exudation of lymph. . . . From the pharynx it may spread down the trachea and into the bronchi. So that in diphtheria we get not unfrequently membranous inflammation of the larynx. But membranous inflammation of the larynx, I have told you, is croup. Is there, then, a membranous inflammation of the larynx distinct from the acute specific disease, diphtheria? Are there a true croup and a diphtheritic croup? Certainly, if you were to place in the hands of the best pathologist the larynx of a child who had died from membranous inflammation of the larynx, the so-called idiopathic croup, and that of one who had died from a true diphtheritic inflammation of the larynx, he would be unable to distinguish the one from the other. There is no anatomical character by which he could say, 'This is true croup; this is diphtheritic inflammation of the larynx.' But it is beyond question that true diphtheritic inflammation may be limited to the larynx; that in exceptional cases the pharynx escapes the exudation. Seeing, then, that there

are no anatomical characters to distinguish the one disease from the other, are there any clinical characters by which the two affections may be separated? It has been supposed that the presence of albumen in the urine would be sufficient, and I formerly laid much weight on this distinction. But later years have satisfied me that in cases which present all the characters of true croup, which are sporadic, spread to no other person in the house, come on apparently from exposure to cold and damp,—that in such cases albumen may be present in the urine. It has again been urged that true croup has no tendency to spread; but this manifestly should no more separate a single case from the diphtheritic croup than should a single case of scarlet fever, because it did not spread, be separated from other cases of scarlet fever. The cause, again,—the fact that some cases of croup come on after distinct exposure to cold and wet,—cannot be sufficient to separate croup from diphtheritic croup, for it is beyond question that a considerable number of cases of diphtheria do, to all appearance, at least, date their origin from exposure to cold and wet. I have seen several solitary cases of true diphtheria thus originating, not spreading, or spreading to other persons in the house, as the case may be. So my opinion has undergone some modification, and I am inclined now to the belief that there is no such disease as idiopathic simple membranous inflammation of the larynx. I say I am inclined to this belief. I am not sure that it is true; but, as I formerly thought that the weight of evidence was in favor of their non-identity, I am now inclined, from my further experience, to think that the two diseases are really identical; that the so-called true croup is really diphtheria."

It will be seen further on, however, that this bias of opinion is sufficiently strong to make him willing to base his therapeutics upon it. "But, believing, as I now do," he says, in regard to diagnosis, only a few paragraphs after this modest disclaimer of positive decision of the question, "believing, as I now do, that all croup is but a local manifestation of the general disease, diphtheria, it would matter but little, as regards the diagnosis, whether the pharynx were the seat of membranous inflammation or not. . . . Holding the views which I now do, you will see at once that I should discard from the treatment of croup all those heroic remedies that were formerly regarded as indispensable,—leeching, mercurializing, antimonizing,—and I should advise you to treat it on the same principles as you would treat diphtheria with exudation commencing in any other part."

No comment is necessary as to the deference which is deservedly paid to the opinions of the distinguished man just quoted, especially in regard to this class of diseases, in his own country.

Not less clear and pronounced is the testimony borne by Dr. George Johnson, in the same number of the *Lancet*, in a paper on "Certain Points relating to the Etiology, Pathology, and Treatment of Diphtheria." . . . "I wish to express emphatically my entire concurrence in the conclusion long since arrived at by Bretonneau, Trousseau, and all

the leading French pathologists, that all cases of so-called croup which are associated with the formation of false membranes in the air-passages, are essentially diphtheritic; and, on the other hand, that what we in this country call inflammatory croup or catarrhal laryngitis never results in the formation of false membrane. It is surprising that practitioners of large experience can have any doubt upon this subject; yet we find even in some of the most recent English text-books that perplexing attempts are made to distinguish between what the authors call 'true membranous croup' and diphtheritic croup. The attempt is hopeless and most confusing to the student, for it is certain that membranous croup and laryngeal diphtheria, as we now see them, are one and the same disease. . . . If, as some writers suggest, there be a form of membranous croup which is neither the result of simple inflammation nor of the diphtheritic poison, I can only say that I have never met with the disease."

PHILADELPHIA, May 17, 1875.

TRANSLATIONS.

RHEUMATIC FACIAL PARALYSIS.—Prof. Erb, of Heidelberg, describes (*Deutsches Archiv für Klinische Medicin*) three clinical varieties of rheumatic palsy of the portio dura, essentially differing in severity, duration, and amenability to treatment. Electricity, the general therapeutic resource in this affection, he considers as affording also valuable aid in the diagnosis and prognosis; as the individual cases show striking points of difference in the behavior of the affected nerve and paralyzed muscles under the galvanic and faradic currents.

In a certain proportion of cases the electro-excitability of the nerve and muscles remains completely normal during the entire course of the disease; perhaps, on the second or third day, there is slightly increased sensitiveness, but it is transitory and shortly disappears; at no time is there any decrease in the qualitative or quantitative electrical reaction.

The electrical condition, in another set of cases, differs most characteristically from the preceding. The nerve, in a few (four to six) days after the onset of the disease, shows a rapid decline in its response to the application of the faradic and galvanic currents, so that soon after (ninth to twelfth day) the electro-motility is completely lost, and generally so continues until the return of some power of voluntary motion, when it slowly resumes its normal state. Meanwhile, important changes occur in the muscles; the faradic electro-muscular contractility lessens, until it finally disappears, as in the nerve; but though the susceptibility to the galvanic current sinks to a certain point in the first week, in the course of the next, or in the third week, it increases to far above the normal, and undergoes material qualitative changes: these anomalies disappear only very gradually and slowly. The clinical course of this variety assimilates the results produced by experimental destruction or division of the trunk of the facial nerve in animals, and the author, on that account, considers that when they occur, a complete degeneration, resulting in the loss of the electro-excitability of the nerve, is present, and that only with such an alteration would these characteristic changes occur in the muscles, which symptoms he groups, for this reason, under the title of the "degeneration-sign" (*Entartungsreaction*). Thus

is this form, which he terms the "severe form," in contradistinction to the first, characterized in a manner most marked and evident. Although it is not fully matured until the termination of the second or in the course of the third week, yet, if during the first, or at its end, a marked sinking of the farado-excitability of the nerve occurs, the subsequent changes may, generally speaking, be predicated with certainty, and the diagnosis made definitely between this and the light form in which the electrical condition is normal throughout.

The prognosis of the "light form" is absolutely favorable. In the course of three or four weeks recovery will take place, independently of treatment, and with or without electricity. This class of case is sufficiently large to correct the still prevalent but erroneous idea that the early application of electricity may change a light form of facial palsy into a severe one; it likewise controverts the opinion of C. Paul, that a facial paralysis that first comes under electrical treatment after the tenth day will be tedious and stubborn.

Experience teaches that in all those cases which show the "degeneration-sign," the prognosis is relatively an unfavorable one; the disease lasting from weeks to months, and, in many cases, after years have passed traces of the paralysis will be still evident in the features. This is properly termed the "severe form," and it is well, when treatment is commenced, to warn the patient of the possibility of a long duration of the disease. It is so much the more needful because we are unacquainted with any remedy that is in a position, with any certainty, to shorten materially the wearisome course of the disease, electricity not excepted.

Abundant experience, confirmed by careful observation, teaches, however, that exceptions occur, and that there is yet another class, which occupies an intermediate position between the two mentioned, in reference to the electro-dynamic changes and the duration of the disease. This "middle form" is characterized by the appearance of only an unimportant decrease, but never a complete loss, of the faradic and galvanic excitability of the nerve; whilst, apparently, the electrical condition of the muscles passes through the same changes as in the severe form. The prognosis of cases of this kind is also favorable; recovery follows in a few weeks, but not so soon as in the light form.

To distinguish these three forms in practice with any certainty, requires careful electrical examination. With the induced current, however, the severe form may be distinguished from the other two, at the end of the first week, by the material or complete loss of the irritability of the nerve. It is more difficult to pronounce between the others; but if the response to the current at the end of the first or beginning of the second week be positively though slightly reduced, the middle form is present; if it remain normal, we have to deal with the light form. The course of the succeeding week, at all events, will verify or correct the diagnosis.

In seeking for an explanation of the fact that in the mediate form such marked change may occur in the muscles without alterations in the nerve of corresponding gravity, the author refers to some physiological experiments made by Ziemssen and Weiss, in which the results were analogous to the symptoms occurring in this form. These observers found that a light contusion of the nerves caused a transient paralysis, which passed off in a few days, during which the faradic excitability of the nerve sank a little but was not lost, whilst the increase and qualitative changes occurred in the muscles just as in the cases of degeneration of the nerve. Unfortunately, the histological observations in connection with these experiments were never published.

The author next takes up the question as to whether it is possible to locate the exact anatomical position of

the nerve-lesion producing the paralysis. It is generally conceded that this cause is a peripheral one, that the nerve is affected after it leaves the brain, and from the fact that, soon after its exit from the stylo-mastoid foramen, the nerve breaks up into the facial branches, all of which are generally involved in this disease, it is considered that the nerve must be affected in the Fallopian canal or in its immediate vicinity. He then takes up in succession the different branches given off at known intervals from the nerve; and, since destruction or disease of the nerve-trunk at any one point would cause paralysis of the branches below that point without involving those above, he proceeds to consider the probability of determining the site of the lesion in any individual case by means of the participation, or not, in the paralysis of these different branches of the nerve.

This leads him into a discussion of the function of each branch, and into quite an extended and interesting one in reference to the anatomy of the chorda tympani nerve. After carefully reviewing the question and referring to numerous recorded cases, he concludes that the weight of testimony is in favor of Schiff's view: that the filaments of the chorda tympani, after being received by the trunk of the facial from the lingual, apparently pass out again from the facial at about the level of the geniculate ganglion (*intumescentia gangliiformis*) and return to the trigeminus, apparently, by several routes (greater superficial petrosal nerve, spheno-palatine, and otic ganglia, etc.), and, with its trunk, return to the brain. What in detail these routes are in the human economy does not seem to be sufficiently established: apparently, individual peculiarities exist; it is possible that in some a part of the fibres take a peripheral course and return to the trigeminus by means of the inosculation existing between a branch of the facial and the auriculo-temporal branch of the fifth. This would appear to have been the condition in two surgical cases, where, after extirpation of the parotid gland, some impairment of taste appeared in the anterior two-thirds of the corresponding half of the tongue; however, as it is not stated how soon this occurred after the operation, it may have been due to an acute neuritis ascendens of the trunk of the facial, which secondarily involved the chorda tympani.

He concludes that in many cases of facial paralysis it is possible to locate the lesion approximately, although it is evident that such a pathological process would not necessarily be limited to one point, but might, in the course of the disease, extend along the nerve, or even affect a considerable portion of it, so as to give the appearance of being localized in several spots. From numerous observations, however, he draws the following practical deductions:

1. Disease of the nerve-trunk outside of the Fallopian canal will give the following symptoms: paralysis of the nerves of expression without involvement of the posterior auricular branch, or disturbance of taste or hearing, or the salivary secretion, or the position of the soft palate, etc. In exceptional cases impairment of taste may occur from the centrifugal course taken by the filaments of the chorda tympani, as before mentioned.

The cases of the "light form" belong probably to this class, and therefore, in making the prognosis, special attention should be given to the condition of the posterior auricular nerve (distributed to the *occipitalis retrahens auriculæ*, etc.).

2. Disease of the nerve in the Fallopian canal, but below the point of entrance of the chorda tympani, is shown by palsy of the features and of the posterior auricular nerve without affecting taste, etc.

To this class the greater number of the cases of the severe form appear to belong.

3. Disease of the nerve between the chorda tympani

and the stapedius is characterized by paralysis of the external branches and posterior auricular, with anomaly of taste in the anterior two-thirds of the corresponding half of the tongue, but no trouble of hearing, etc.

4. Involvement of the trunk of the nerve from the stapedius to close under the geniculate ganglion adds to the foregoing diminished action of the salivary glands increased sensitiveness in the hearing for high notes (*hyperacusis*, *oxyokoia* of Wolff), but no irregularity of the soft palate.

5. When the disease affects the locality of the ganglion itself, the point of departure of the greater superficial petrosal nerve, which, besides the major portion of the filaments of the chorda (on their route to the trigeminus, by way of Meckel's ganglion), carries the motor fibres for the palate, there is paralysis of all the external branches, impaired taste, and salivary secretion, abnormal sensitiveness of hearing, and lateral deflection of the palate. This is the only point at which these two bundles of nerve-fibres come in contact with each other.

6. A lesion above the ganglion, between it and the brain, would affect all the external and internal branches, as just above described, except that there would be no impairment of taste. Some few cases of this character have been reported by Ziemssen, Landowzy, Romberg, Bucklinmaier, and the author.

Prof. Erb remarks that these observations are not only available in determining with some certainty the seat of the lesion in facial palsy, but also would render valuable aid, from the involvement of the *portio mollis* and other nerves at the base of the brain, to the differential diagnosis of diseases of the neighboring organs, in similar affections of the middle ear, the mastoid and petrous portions of the temporal bone, the parotid gland, etc.

As to the relative frequency of these different varieties, the author arrives at what he considers a no less conclusive than striking result. In thirty-five cases coming under his own observation, twenty-three occurred in which, beyond paralysis of the external branches, no further symptoms were present. These cases, therefore, pointed to a lesion below the junction with the chorda tympani. Four cases belonged to class two; five to class four; a single one existed where the level of the ganglion was the seat of the trouble; and two cases, finally, belonged to class six.

The proportion of cases belonging to the first group is, apparently, from the literature of the subject, in reality even larger than the above would indicate, as the cases of facial paralysis without accompanying symptoms are certainly much more seldom reported than those in which they do appear.

It would hence appear that rheumatic facial paralysis is an affection which, as a rule, involves the nerve-trunk below the chorda tympani,—i.e., at the lower end of the Fallopian canal, or immediately outside; and which, in a certain number of cases, extends to the chorda and the stapedius, more rarely to the geniculate ganglion, and only exceptionally, or never, affects the nerve-trunk at the base of the skull. Following the general view that such rheumatic processes are usually of the nature of a light inflammation of the neurilemma, we would then consider this disease as a neuritis facialis, limited, as a rule, to the nerve at its point of exit from the stylo-mastoid foramen, or its immediate vicinity, and which may ascend more or less far along the nerve in the Fallopian canal. The narrowness of this passage will then easily explain how an inflammatory swelling of the nerve-sheath, insignificant in itself, so frequently leads in this situation to such injurious compression and obstruction of the nerve as to find its clinical expression in the "degeneration-sign."

The author thinks that the "light form" has its

cause outside of the Fallopian canal (class one), and hence the nerve is free from the strong compression and its serious results. If the nerve be affected just inside the foramen, the "severe" or "middle" form appears according to the amount of the unavoidable compression. This would seem to be confirmed by the author's experience, as in all his cases where he suspected the presence of the severe form, the posterior auricular branch was found to be involved.

If the preceding views are correct, electricity affords a convenient means of determining more exactly the position of the exciting cause of the paralysis. If the electro-motility is unaffected (light form), the disease is to be sought for outside of the stylo-mastoid foramen; on the contrary, if the "degeneration-sign" appears (middle and severe form), then the pathological process is located inside of the Fallopian canal, and the prognosis will depend upon the amount of injury suffered by the nerve, as indicated by its behavior under electrical stimulus. F. W.

VICES OF CONFORMATION OF THE ANUS.—At a meeting of the Société des Hôpitaux, M. Verneuil reported upon two observations presented by M. Deleus relative to malformations of the anus. In the first of these cases the anus presented two orifices separated by a vertical septum; one of these led into the rectum, while the other terminated in a cul-de-sac in the pelvis. Excision of this septum was performed.

M. Verneuil added to this observation the following one: an infant five months old, having some difficulty in defecation, was sent to the Lariboisière. Having ascertained the presence of a raphé proceeding from the scrotum and separating two orifices which led to a common anus, the surgeon made an incision, and found a stricture of the rectum, which was remedied by the daily introduction of the finger as a dilator morning and evening. After a few months, dilatation was complete, only two small tubercles remaining on the anterior and posterior walls. M. Deleus' second observation related to a young child with imperforate anus. The operation was performed immediately, and was facilitated by resection of the coccyx. The cure was rapid, but three months later prolapse of the rectum took place, which seemed irreducible. This prolapse may have been due to taking away the support of the sphincter, but Dr. Verneuil, who had performed a similar operation several times successfully, believed it due to bad hygienic conditions.—*Bull. Gén. de Thérap.*, April 30. X.

SUDDEN DEATH FROM PAIN IN A WOMAN WITH HYDATID CYST OF THE LIVER.—At a meeting of the Société des Hôpitaux (*Bull. Gén. de Thérap.*, April 30), M. Desnos read an account of a case occurring under his care at the Hôpital Necker, in 1865.

The patient had a very voluminous hydatid cyst of the liver, for which, without previous puncture, the Vienna paste was applied.

The evening following this application the woman died suddenly, and at the autopsy no trace could be discovered of either peritonitis or of perforation of the cyst; clots were found in the heart. It was evident that the woman had succumbed to a syncope provoked by the intense pain caused by the caustic,—a syncope superinduced by the profoundly cachectic condition of the patient. M. Desnos compared this case to one reported by M. Martineau, which differed, however, in the fact that death was brought about by an intense pulmonary congestion. This difference perhaps depended upon the circumstance that in M. Martineau's case the pneumogastric nerve was touched directly, while in that of M. Desnos the effect was upon the nerves of the life of relation. X.

CASE OF COMPLETE INVERSION OF THE UTERUS.—Dr. S. Voelkel contributes the history of such a case to the *Berliner Klin. Wochen.*, March 15, introducing it by a few remarks relative to the comparative rarity of the accident.

Partial inversion is frequently reported in the medical journals; but complete inversion, especially occurring so long after confinement as in Dr. V.'s case, is seldom met with.

Dr. Voelkel's patient was a healthy primipara, 32 years old, whom he had delivered, after a somewhat protracted labor, by means of the forceps. There was some slowness in contraction on the part of the uterus, but by proper management the placenta was expelled, and the uterus contracted satisfactorily, remaining in good condition for two days. At the end of that time Dr. V. was summoned in great haste, and found the uterus exposed to the air, completely inverted, and the patient nearly dead from hemorrhage. Application of the proper remedies, stimulants, etc., was made, and the patient subsequently recovered. X.

POISONING BY POPPY-HEADS IN AN INFANT CURED BY INJECTION OF COFFEE.—Dr. Kobryner communicates the following case to the *Bull. Gén. de Thérap.*, April 30. He was called to see an infant scarcely three weeks of age, to whom its mother had administered an infusion of poppy-heads with the view of procuring sleep. The child lay pale, immovable, the pupils strongly contracted, almost effaced; the extremities cold; the lips cyanosed. The radial pulse was imperceptible; auscultation alone showed that life still existed. Syrup of ipecac, given by the mouth, failed to produce vomiting. Strong infusion of coffee was then injected into the bowel, while sinapisms were applied to the arms and legs. This procedure was continued for some hours before the little patient showed any sign of life. Finally, however, the pulse reappeared, the cyanosed condition diminished, and eight hours after the commencement of the treatment the child was out of danger.

The quantity of infusion of coffee injected during this period amounted to six pints, at least five pints of which were retained. The following day the child appeared as well as before the accident. X.

VACCINATION WITH FATAL RESULT.—Krügkula (*Wien. Med. Wochenschr.*, No. 47, 1874) inoculated eight soldiers with vaccine lymph from a foundling-hospital. In two there was no result. In the other six, in whom the vaccine pustule became quickly developed, there occurred chills within twenty-four hours, followed by high fever, weakness, and delirium.

Two to four days after the vaccination, phlegmonous inflammation of the upper arm appeared, in some on one arm, in others on both, which, after a few days, became gangrenous. Two patients were cured, four died. From the same source nine vials were filled with vaccine virus, the use of which caused no evil effects.—*Centralblatt*, March 13. X.

BROMIDE OF LITHIUM.—M. Rouband draws the following conclusions from his investigations of this drug. Bromide of lithium, as a medicine, has a double effect. It possesses, in a high degree, those lithotropic properties attributed to the salts of lithia, and, in addition, like other bromides, affects reflex sensibility most energetically. It has not, however, the inconvenient action on the heart displayed by bromide of potassium. Consequently, its place in therapeutics is in the first rank among lithiatics and among sedatives, and its action is particularly valuable in the uric acid diathesis, which is accompanied by painful symptoms, and in neuroses which are so often complicated by the presence of uric acid.—*Bull. Gén. de Thérap.*, April 30. X.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JUNE 5, 1875.

EDITORIAL.

WHY IS IT?

THE Medical Department of the University of Pennsylvania is over one hundred years old, and its professors during the century have filled the world with their personal fame, and made the name of their institution respected wherever learning bears honor. The Scientific Department of the same university was born just three years ago, and, able and learned as are its faculty, is of course comparatively unknown.

The Medical Department of the University, save only in the cabinets which have been bestowed upon it by its professors, is as poor as it was on the day of its birth, not having accumulated one dollar of endowment during a century of most flourishing life. The Scientific Department of the same institution has, during its brief life, obtained immediately available endowments amounting, it is believed, to nearly half a million of dollars, and reversionary rights in estates which, it is said, will be worth in a few years as much more.

Surely this contrast ought to make every lover of medical progress, every believer in his profession, pause to discover why it is.

The reason which we have frequently heard assigned is, that the community is given up to the worship of the mechanic arts and applied science, and does not care for medicine or its interests.

This answer may seem at first plausible, but it is really no better than the plaint of the poor artist, that "the world does not appreciate him." The

world cares for nobody, but the world does care for whatever is of value to it; and if this or any other community does not appreciate the medical profession it is because the profession is of no value to it.

It is folly for the profession, and especially for the medical colleges, to account for failure by blaming a community. Just so soon as any one paints good pictures, men will desire them. Especially is it folly in such an institution as the Medical Department of the University of Pennsylvania to lay its poverty to the indifference or niggardliness of a community which has given millions for every conceivable object of charity. Folly, when we recall the towering influence in this community of such men as Rush, and Physick, and Morton, and Parrish, and a host of others, living and dead, who have been connected with this medical department. Folly, under the light of the recent success of a few of the alumni and the professors in raising nearly three-quarters of a million in three or four years for a University hospital.

Instead of looking upon the outside, and laying the blame there, it were better to look upon the inside to find why it is the Medical Department has been so neglected. In doing this, let us also not lose sight of the fact that the Medical Department of the University is simply the type, as she is the mother, of American medical schools: *ex uno disce omnes*.

In an ordinary institution for higher teaching, the theory of constitution is that education is a sacred duty of the community to its members, but can never be made to pay, and must, therefore, be supported either by State aid or by endowments. Unfortunately, or perhaps fortunately, in this country public opinion has generally been opposed to State aid to the highest institutions of learning,—the theory, apparently, being that all citizens should be brought by the State to a certain level and then left to themselves. Public-spirited individuals are more and more supplying this lack of State aid by gifts and legacies amounting in the aggregate to enormous sums. Now, we conceive that the ordinary medical college is so essentially different from other educational institutions in its organization that it can never be classed with them as an eleemosynary institution or attract endowments; and that this is the only reason that none of our medical schools have ever obtained any endowment in this country.

A number of medical gentlemen get together, apply to the Legislature for the right of giving a medical degree, and then produce an annual crop of doctors. Such is the brief history of the rise of a medical school. There are two distinct functions

performed by its professors,—educating in medicine, and giving the right to practise medicine. It is not the first of these that the average student cares for solely, or even chiefly; it is the second that he wants.

If any man doubts this, let him ask himself how many students would any institution get which simply taught medicine and did not give a degree.

It is plain that the medical institution holds a valuable franchise from the Legislature, and expects to make the degrees pay for the medical teaching. The faculty is therefore pretty much on the platform of a firm united together for the purpose of profit. In an institution like Bellevue Medical College, where the faculty is self-appointed, the parallel is exact. In the University or the Jefferson Medical College, the only difference is that the firm has for its supposed advantage given up the power of selecting its own members. Under these circumstances it would be absurd to expect philanthropists to give money to endow medical institutions: as well might they add to the capital of Wanamaker & Brown, P. T. Barnum & Co., or any other combination of men engaged in a laudable effort for gain.

In order to bring the medical colleges into their proper sphere of being simply schools of learning, the various Legislatures ought to take away their power of giving the right to practise, by creating State Examining Boards. But the colleges have it in their own power to place themselves in a position to obtain endowments without any legislative aid. Let them reform medical education by lengthening their courses and raising their standards, and then say to the public, "Medical teaching, properly carried out, can never be self-supporting; we appeal to you for endowments." If this were done, and the enormous influence the profession wields in the aggregate brought to bear, American medical colleges would lead the van, and would not be a by-word and a scoff among the institutions of learning.

CORRESPONDENCE.

BALTIMORE, May, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—It is generally well known that we have in this city two corporations, known to the law as Johns Hopkins Hospital, and Johns Hopkins University. Mr. Hopkins endowed these two institutions with about six millions of dollars, and ever since his death considerable interest has been shown as to the manner in which the two boards of trustees intend to carry out the designs of the donor. The Hospital Board purchased the building and grounds of the old

Maryland Hospital for the Insane, demolished the building, piled up the bricks, and rested from their labors, so far as the public could see. This does not necessarily imply that nothing is doing, for we understand that thorough examinations have been made of the principal hospitals in this country and Europe, so that a plan combining all the latest scientific improvements may be selected. It is said that the preparation of a plan is far advanced, and that we may soon expect the buildings to be erected. The University has not progressed very far. Prof. Gilman, of the University of California, has been selected to preside over our new institution. He has been in the city for some weeks past, and a temporary home for the University has been purchased, at a cost of \$75,000, on Howard Street, adjoining the new City College. It is said that a proposition has been made to raise the grade in the City College and place it under the University as one of the under-graduate schools. I asked a prominent medical gentleman when he thought the new University would go into operation. He said that "forty generations of worms will feed upon the body of Johns Hopkins before a student enters the doors of the Hopkins University."

There has been much discussion in the papers concerning the character of the proposed school. Because Mr. Hopkins made provision for the gratuitous education of a certain number of students from Maryland, Virginia, and North Carolina, many contend that the course of instruction should be the same as that of our ordinary colleges. We have several colleges of low grade, in which there are free scholarships, and it would seem to be useless to add to the number. The magnificent endowment of the Hopkins University places it in the power of the Board of Trustees to establish an institution which may be a credit to the State and nation. With the funds at their disposal they can command the best men of the country, if not of the world, to fill its chairs; and if the chairs are so filled the students will come. Of low-grade schools and so-called colleges the country has more than enough; of high-grade schools and real universities it has too few. Properly established, there is nothing to hinder the Hopkins University standing at the head of American educational establishments and rivalling those of Germany. As yet, there has been nothing done in regard to the schools of law, theology, medicine, etc. The main question has been to decide whether it shall be an under-graduate or a post-graduate school; whether professors shall be employed on account of their ability to hammer a "little Latin and less Greek" into unwilling college boys, or whether men of established reputation shall have an opportunity to teach their specialties to men capable of understanding and appreciating the instruction. The medical department, if favoritism does not control the selection of the professors, with the Hospital and Convalescent Home as clinical fields to supplement the didactic lectures, ought to become the leading college of the country and afford as good opportunities for obtaining a thorough knowledge of

medicine in all its branches as London, Paris, Berlin, or Vienna.

President Gilman desires the university to be *the* school of the country, and it is to be hoped that nothing may prevent him accomplishing his desire in this respect.

Baltimore is celebrated for the neglect given to sanitary matters. Dickens must certainly have had us in mind when he sketched the "Circumlocution Office," or "how not to do it." For two summers we have endured the intolerable stench of the basin, and it now begins to infect the air. Many plans have been proposed for abating the nuisance (filling up, pumping out, flushing, emptying disinfectants into it), but our city fathers have not advanced beyond the talking stage. And, as if the basin was not enough, we are still blessed with the night-artillery and the bucket-brigade. By what means a thousand men can rule a city of three hundred thousand, and make it endure the vilest odors, is unknown to me, but of the fact we are, alas! convinced. Bah!

Yours, etc.,

MEDICUS.

NEW YORK, May 24, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

SIR,—In the *Times* for May 22, 1875, p. 536, you announce the discovery by Hoppe-Seyler of urobilin among the products of decomposition of blood coloring-matter. This was discovered by myself, and announced two years ago ("Guide to Urinary Analysis," p. 24, note, New York, 1873), as follows:

"As these pages are passing through the press we have met with spectroscopic evidences corroborating the view that the urine-pigment is a derivative of the coloring-matter of the blood, by the discovery, in a solution of decomposing hæmoglobin, of a broad but distinct band of absorption between the Fraunhofer lines *b* and *F*. This line appears to be identical in position and character with the band discovered by Jaffe (*Virchow's Archiv*, B. 47) in urine and in solutions of urobilin. In the solution of hæmoglobin referred to, the new band was accompanied by the two oxygen blood-bands (between *D* and *E*), and also by the methæ uroglobin band (between *C* and *D*). This association gave a four-banded blood-spectrum, differing from any that we can find on record, and the composite nature of which was evident."

Respectfully, H. G. PIFFARD, M.D.

IRRIGATION OF THE BLADDER.—Dr. Rose, of New York, calls attention, in the *Medical Record* of May 8, to Zeissl's method of introducing liquids into the male bladder without the use of the catheter. The plan is to fit the point of an irrigator into the mouth of the urethra, while the patient is placed on his back, with raised nates, the penis being stretched along the abdominal walls. By the employment of this method Dr. Rose was enabled to inject the bladder with a solution of tannin, having introduced a glass tube into the urethra and connected it with a fountain syringe, which was raised to the height of four feet. Previous attempts to wash out the bladder by means of a catheter had been unsatisfactory.—*Boston Medical and Surgical Journal*.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, MARCH 25, 1875.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

Multiple hernia.

DR. DE F. WILLARD presented the specimen, which was obtained from A. B., a woman æt. 40. She has had femoral hernia for eight years, wearing a truss, and suffered no serious inconvenience until 6 A.M. on the 27th of January, 1875, when she found that the intestine had protruded and could not be returned. Pain commenced about 8 o'clock, soon after which unsuccessful efforts at taxis were made by a physician. She was admitted to the Presbyterian Hospital at 1 P.M. on the same day. Dr. H. Lenox Hodge attempted reduction, both before and after drawing off the gases, by an aspirator, but both efforts proved unavailing, and by 9 P.M. the loop of intestine had again become greatly distended. The pain, vomiting, etc., became more and more serious, and at 1 A.M. the ordinary operation for the relief of strangulated femoral hernia was performed by Dr. H. It being necessary to open the sac, the bowel was found deeply congested, but its vitality was good, and it was carefully returned into the cavity of the abdomen.

The patient reacted well, but in twelve hours tympanitis appeared, the pulse became rapid and feeble, while nausea, vomiting, and the usual symptoms of peritonitis soon supervened.

Upon the second day she aborted of a two-and-a-half months' fœtus,* after which the symptoms grew rapidly worse until she died, about forty hours after the operation.

Upon examining the cavity of the abdomen, a small amount of effusion was found present, but the existence of general peritonitis was evidenced by lymph glueing together all the intestines and covering in the uterus. The loop of intestine was still in the bent condition in which it was returned, being held loosely by soft lymph, but its calibre was perfectly patulous, and, though congested, it was not at all gangrenous. The internal crural ring was blocked by a mass of fresh lymph, but bore no evidence of being the centre of inflammatory action.

Upon examining the opposite side, it was found that a large loop of the omentum had passed through the left internal abdominal ring, and was fastened in the canal; while at the thyroid foramen existed another epiplocele, the omentum having passed out alongside the obturator vessels to the extent of one and a half inches.

Dr. W. G. PORTER said he was present at the operation. Great efforts were made to reduce the hernia without opening the sac, but this was impossible, and, on opening the sac, numerous adhesions were found.

Cystic medullary cancer of testicle.

Dr. W. S. FORBES presented the specimen, from a man aged 54 years. The patient related that, two years and five months prior to his entrance into the Episcopal Hospital, he had fallen in a fit, and that a few days after the catastrophe his scrotum began to enlarge, and that in a short time it was as large as when the operation for removal of the testicle was performed a few days ago.

On examination, the scrotum measured eleven inches

* This accident was entirely unlooked for, as she had been a widow for five years.

in its vertical or long axis, and eight inches transversely. It presented the appearance of a large hydrocele. The upper half of it was translucent, and the lower part opalescent and thick. The man was very much out of health, and very despondent. There was strongly suspected a diseased testicle at the lower part of the mass. In a short time the opacity of the tumor extended over two-thirds of the scrotum. It was concluded that there was a condition of cachexia, as a consequence of which a blood-vessel had ruptured into the sac, producing the appearance so well described by Percival Pott as sometimes occurring when the walls of a hydrocele become much distended.

On tapping the tumor, very little blood and very little water were drawn off through the canula, although the instrument could be moved about with great freedom, imparting the sensation that would be given in moving it through clots of blood, which strongly suggested hæmatocele. The patient was advised to have the tumor removed, to which he readily assented.

At the consultation with his colleagues, Dr. F. stated his belief in the existence of hæmatocele complicated with malignant disease of the testicle.

On opening the mass, a large quantity of blood and water escaped from the cyst at the upper part, and the testicle was found in the lower part as large as a large orange, and presenting the appearance of medullary cancer.

The history of this case seems to be this: that the man bruised his testicle in the fall he had more than two years ago, that hydrocele was rapidly developed, that the injured testicle was attacked by malignant disease, and that there was ruptured a blood-vessel by distention, giving rise to the opacity in the fluid in the cyst some weeks ago.

The peculiarities of the case are that the patient should have lived over two years with this malignant disease, and that there should have been no metastatic complication, for every other portion of his body appears to be healthy.

The PRESIDENT said he presumed that, as usual, the character of the patient was such that the history could not be relied upon. He thought it quite likely that a large blood-clot had formed, from which the organic parts became removed, and a cystic transformation of the clot occurred. Such a history as this he thought not improbable.

Dr. FORBES replied that not only was this the man's story, but that his wife also insisted upon its accuracy. He had himself no doubt that a decided change had taken place in the tumor since the man fell in convulsions, and also that the testicle was injured at that time; and the growth was, moreover, evidently not recent. It is generally the characteristic of medullary cancer that it grows rapidly, that it is then, perhaps, stationary for a time, and that it finally again grows rapidly, carrying off the patient. From the man's family he could get no other history than that the tumor had been as large for two years as on the day it was removed.

The PRESIDENT asked whether the patient was epileptic.

Dr. FORBES replied that he was not.

The specimen was referred to the Committee on Morbid Growths, which reported, April 8, 1875, as follows:

"In Dr. Forbes's tumor of the testicle we find, upon microscopical examination, large oval alveoli, filled with nucleated epithelial elements; the latter are seen in the various stages of fatty metamorphosis. There is no cylindrical arrangement indicating the presence of any remaining seminiferous tubules, nor is there any proper intercellular substance. The growth is a medullary carcinoma."

Enormously enlarged spleen.

Dr. W. G. PORTER presented the specimen, from Mrs. H., white, United States, married, about 40 years of age, mother of five children, the youngest now seven years of age. She always enjoyed good health until 1865, when she went to Norfolk, Virginia, where she contracted a very obstinate form of malarial fever, for which she could never be induced to submit to regular treatment. She never would take quinine, or, in fact, medicine of any kind for any length of time. About 1868 she had a fall, when she felt, as she expressed it, "something give way," and soon began to feel pain in the left side in the region of the spleen, which was accompanied by acid eructations, and considerable gastric and intestinal disturbance. Soon afterwards, a tumor was noticed in the epigastric and left hypochondriac regions, which gradually increased in size until it filled the whole abdominal cavity. About eighteen months ago she was examined by Dr. F. J. Buck and Dr. John S. Parry, of this city, who pronounced the tumor to be an enlarged spleen. She was treated locally by the biniodide of mercury ointment, and the bromide of ammonia internally. Before and since that time she had been treated by many regular physicians; also by homœopaths, and every other variety of quacks; several of whom pronounced it to be an ovarian tumor, and one of whom assured her that the tumor was ovarian, and was very anxious to remove it, assuring her that he could remove it almost without her feeling it. On Friday last, she not only attended to her household duties as usual, but visited an administrator of oxygenated air, who promised to cure her in two weeks. She also attended a furniture-auction, and was on her feet the greater part of the day. On Saturday she complained of great abdominal pain and some difficulty of breathing, which was greatly increased by the recumbent posture.

On Sunday night Dr. Porter saw her for the first time, and found her sitting propped up in bed with pillows, complaining greatly of pain in the abdomen and a feeling of tympanitic distention. Her stomach was very irritable, and she had vomited large quantities of a greenish, bilious-looking fluid. She was much emaciated and thoroughly anæmic. The pulse was weak, and she was evidently extremely ill. Morphia was administered hypodermically, followed by hot applications to the feet and brandy and chlorodyne by the stomach. The anodynes had but little effect in relieving the pain, and on the following day she died.

Autopsy, thirty hours after death.—Body extremely emaciated; abdomen very much enlarged and distended. On opening the abdomen, it was found to be almost entirely filled by a large tumor which lay immediately under the peritoneal coat of the abdominal walls and in front of the intestines. On lifting it up, it was at once seen to be the *spleen*. There were no adhesions between it and the abdominal walls. The weight of the organ on removal was found to be *twenty-one pounds*.

The PRESIDENT said the spleen was the largest ever presented to the Society, and asked Dr. Porter whether there were any adhesions, to which the doctor replied that there were none.

The PRESIDENT said the exhibition of such a tumor brings up the question of extirpation of the organ involved. The absence of adhesions observed here is frequently observed in connection with malarial disease; the changes in the peritoneum being limited usually to capsular thickening. When the organ approaches at all near the size of the present one, treatment has been heretofore an entire failure, and this has been so well recognized that the possibility of extirpation has often been discussed, and the operation actually performed in several instances. As to other forms of

treatment in less advanced cases, hypodermic injections of ergotin seem to have some influence over the contractile element of splenic tumors, though more evidence is needed before the value of this treatment can be determined. He had recently a case of leucocythæmia under observation where there appeared to be a temporary diminution of bulk under this mode of treatment. All treatment by external inunction and internal use of quinine is successful only in comparatively small degrees of enlargement. He would be glad to hear an expression of opinion, with regard to the propriety of operation, from the surgical members of the Society.

Dr. JOHN ASHHURST, JR., said that it was, of course, well known that splenotomy had been performed with success in *traumatic* cases, but no instance had, he believed, occurred, at least in modern times,* in which success had attended the operation when performed for such a condition of the organ as was exhibited in the specimen on the table; death having, indeed, in these cases usually followed in a short time from hemorrhage. In view of such a history as had been read this evening,—the patient carrying this enormously enlarged spleen for years with comparative comfort, and being able to attend to her ordinary avocations,—the surgeon who should propose to operate would, in Dr. A.'s judgment, assume a grave responsibility. The probability of relief from such an operation was so small as to be totally incommensurate with the risk to life.

Dr. FORBES asked to know the relative size of the artery and vein.

Dr. PORTER replied that they had not been examined to this end, and he could not answer, but the vessels remained attached to the tumor, and could be examined.

Dr. R. M. BERTOLET said that if this huge organ was an *ague spleen*, as had been suggested, he thought it of a rare type, as we usually have more thickening of the capsule than is here found. He thought it remarkable that the organ with such a thin covering did not rupture long before it had attained its present size. Another reason against its being a mere *ague spleen* appeared in the light color it presented instead of the dark pigmented hue of the *ague spleen*. He was also impressed by the waxy appearance of its cut surface and the translucency of its edges, and asked whether the iodine test for amyloid degeneration had been applied.

The PRESIDENT said that he also had been struck with the points alluded to by Dr. Bertolet, particularly as to the translucency of the edges and the absence of capsular thickening, but he was deterred from mentioning them by the fact that the other viscera were uninfluenced. Further, such extreme enlargement of an albuminoid spleen is rare, while there was also the history of persistent malarial disease previous to the appearance of a tumor. The freedom from suffering

and the long maintenance of activity were as remarkable as anything else in the case. In other cases of extreme enlargement, he had observed considerable suffering and great impairment of general health. He shared Dr. Ashhurst's opinion with regard to the impropriety of operating, to a great extent.

Dr. PORTER said that it had changed color since its removal, when it was much darker in hue. It had been preserved in a fluid containing a mixture of salt and saltpetre. The tumor was not diagnosed as an enlarged spleen until eighteen months ago, and Dr. Parry, who made the diagnosis at that time, is now out of town, and no further history could be obtained.

The specimen was referred to the Committee on Morbid Growths, which reported as follows, April 8, 1875:

"The monstrous spleen, presented by Dr. Porter, does not respond to the tests for amyloid reaction. Fresh microscopic sections show the presence of much black pigment-matter in all the splenic tissues. The Malpighian bodies and trabeculæ are not appreciably hypertrophied; the hyperplasia seems to consist solely in an aggregation of blood-corpuscles (chiefly red) in the cavernous sinuses or pulp-substance of the spleen."

Mammary cancer.

Dr. JOHN ASHHURST, JR., exhibited a specimen of mammary cancer, removed a few hours previously from a married woman, 43 years of age. The right breast was the one affected, and the patient, who had borne several children, attributed the formation of the tumor to a blow which she had received upon the part. The disease had lasted about one year, but had been a source of suffering for only four or five months. The nipple was much retracted, partly on account of a previous mammary abscess, and the skin over the growth was becoming adherent, but there were no deep adhesions and no glandular implication. The mass was removed through an oval incision, care being taken to cut wide of the diseased structures and to remove with the tumor much of the surrounding subcutaneous fat.

Latent cirrhosis of kidneys without albuminuria or dropsy; hypertrophy of heart; dyspnoea; sudden death.

Dr. WILLIAM PEPPER presented the heart and kidneys from a case of latent Bright's disease. The patient was a young woman, æt. 27 years, whose appearance always indicated full health, with some tendency to plethora. It is not known that she ever had scarlatina, and no symptoms had ever attracted attention to the kidneys. For some years past, occasional dyspnoea had been noticed, which grew much more severe last fall, when it became constant, and much increased on exertion. She also had occasional violent paroxysms of orthopnoea, resembling attacks of spasmodic asthma, and usually at night, and, on several occasions, hæmoptysis occurred. The secretion of urine was abundant, of light color, and rather low specific gravity; it was carefully examined several times, but no albumen or tube-casts were found. The breathing was very frequent, and there were frequently signs of marked pulmonary congestion. The action of the heart was habitually rapid, but was readily kept under control by moderate doses of digitalis. Physical examination showed a considerable degree of hypertrophy, chiefly of left ventricle. While under treatment, several severe nocturnal paroxysms occurred; and, finally, after having enjoyed an unusual degree of comfort for several weeks continuously, she was seized with symptoms of intense dyspnoea soon after retiring one evening, followed in a few minutes by insensibility, purplish suffusion of face, and death.

At the autopsy, extreme cirrhosis of both kidneys was found; the organs being reduced to about one-third

* This sentence perhaps requires some explanation. Dr. Otis, U.S.A., the able surgical historian of our late war, has, in the forthcoming second volume of the Surgical History (the advance-sheets of which I have had the privilege of inspecting), collected twenty-six cases of splenotomy, of which only six are said to have terminated fatally. Sixteen cases, in which the operation was performed for *traumatic* causes, all terminated successfully. Of the other four cases in which death did not follow, one belonged to the first half of the sixteenth and one to the first half of the eighteenth century; in the third (Dorsey's) the spleen does not (according to the report in Eve's "Remarkable Cases in Surgery") appear to have been actually removed, but, its adhesions having been broken up, to have been placed "as nearly as possible in what I [the operator] conceived to be its natural position;" while the fourth was Pean's famous case, in which a cystic spleen was removed under the impression that it was an ovarian tumor. Six cases have come to light since Dr. Otis's table was printed, of which four (traumatic cases) are said to have resulted favorably, and one in death, while the termination of the sixth has not been published. Thus, there appears to have been no case reported, during the last one hundred and fifty years, of successful splenotomy for leucocythæmic or malarial disease, while there have been, during the same period, at least seven cases in which the operation performed under these circumstances was the immediate cause of death.—J. A., JR.

their normal size. There was intense venous congestion of all the abdominal organs. The *lungs* were deeply congested, but no apoplectic clots were found. The *heart* was much hypertrophied, the walls of the left ventricle being especially affected. The valves were competent, but the leaflets of the mitral were thickened and somewhat too rigid. The right ventricle was not much enlarged, and its full expansion seemed checked by a delicate band, which passed from about the middle of the septum to the outer wall. There were traces of old pericarditis.

Dr. J. H. HUTCHINSON remarked that some years ago he had exhibited two kidneys which had undergone even greater contraction than had taken place in those just presented by Dr. Pepper, the smaller weighing only seven drachms. The patient, an unmarried woman of about 30 years of age, was admitted into his ward at the Pennsylvania Hospital for a slight disease of the skin. Shortly afterwards, most distressing dyspnoea set in, and continued until the occurrence of death, in less than twenty-four hours after the seizure. Owing to an oversight, the urine was not examined during life, but that which was removed from the bladder after death was found to be highly albuminous. Dr. H. afterwards learned, from the gentleman in whose house she had lived for some time as a servant, that she had apparently always enjoyed good health, and that she had at no time presented symptoms which could be referred to disease of the kidneys. He had known of other cases in which distressing dyspnoea appeared to be dependent upon cirrhosis of these organs and was almost its only manifestation.

Dr. DE F. WILLARD said, with regard to the absence of albumen from urine, he was called last summer to a girl who had not passed water for thirty-one hours, and was suffering from uræmic convulsions. He removed a small quantity by the catheter, but found, on examination, that it was non-albuminous, and without tube-casts. The girl died in three hours. He made a post-mortem examination, and found both kidneys extremely contracted, both smaller than those presented to-night. He re-examined the urine drawn by the catheter very carefully, and found neither albumen nor casts. He could learn little of her previous history (she was a prostitute), but it was said that she had Bright's disease. He had previously seen specimens of urine in which a single examination had failed to point out the presence of albumen, which was subsequently found present.

Dr. JAMES TYSON remarked that the cases just quoted illustrated the form of Bright's disease in which it was well known that albumen is present in minimum amount, and, according to some excellent authorities, sometimes altogether absent. He was confident it was sometimes overlooked when present in very minute quantity, and he desired to call the attention of the members to the extreme delicacy of the so-called Helier's test, in which some urine is either placed in a test-tube, and nitric acid allowed carefully to descend the side of the glass until it underlies it, or, what amounts to the same thing, but is perhaps a little more easy of performance, placing some acid in the tube first, and allowing the urine gently to fall upon it, when, if albumen is present, an opaque white band appears at the border between the two fluids. Within the last two days he was enabled absolutely to prove the presence of albumen in two specimens of urine in which the ordinary methods fail to detect it.

Dr. WILLARD said that in his case he had made use of this test.

Dr. PEPPER also exhibited the specimens from a case of *lymphadenoma* in which transfusion had been performed, and which will be published in a later number of the *Times*.

BIOLOGICAL AND MICROSCOPICAL SECTION OF THE ACADEMY OF NATURAL SCIENCES.

APRIL 5, 1875.

DIRECTOR W. S. W. RUSCHENBERGER, M.D., in the chair.

PRESENT, Messrs. Seiler, Neill, McQuillen, Mortimer, Norris, Kenderdine, Buckingham, Shaeffer, Thomas, Walmsley, Trueman, Reed, and Richardson.

The report of the committee to which was referred Dr. J. Cheston Morris's report on one-twenty-fifth and one-fiftieth objectives, recommending it for publication in the *Philadelphia Medical Times*, was read, accepted, and the committee discharged.

Dr. CARL SEILER read an interesting paper "On the Photographic Enlargements of Microscopic Objects" (see p. 563), illustrated by a large number of his beautiful photo-micrographs. He also exhibited a very complete adaptation to the microscope of the photographic camera, constructed by himself, in which the contrivances for manipulating the fine adjustment, and the stage-movements, were particularly remarkable for ingenuity and efficiency.

The communication was referred to a committee composed of Messrs. McQuillen, Corlies, and Shaeffer.

Mr. WILLIAM H. WALMSLEY displayed a fine Ross microscope, with Wenham's new adaptation of the Jackson model.

Mr. WALMSLEY also exhibited a resplendent slide of butterfly-scales arranged by Mr. Harold Dalton, of Havre, representing birds of brilliant plumage, around an iridescent vase; and one of Möller's new 100 diatom slides, upon which each frustule was arranged above its name in the appropriate compartment of a many-celled photograph prepared for its reception.

Captain MORTIMER, a corresponding member of the Section, displayed a slide of arranged diatoms showing a beautiful monogram of the San Francisco Microscopical Society, prepared for him by Mr. Coles, of Liverpool. Captain M. likewise described a very portable pocket-microscope, made by Browning, of London, at the low price of two guineas, which he proposed to bring before the Section at its next meeting.

Dr. J. H. MCQUILLEN remarked that he had had the pleasure of inspecting this ingenious pocket-microscope belonging to Captain Mortimer, and believed that similar instruments would prove very useful, not only to botanists, and, indeed, to naturalists generally, but especially to physicians, who frequently had occasion to investigate specimens of urine, sputum, blood, etc., at the bedside of patients, or under various circumstances where if an immediate examination were not made the operation could not be satisfactorily performed.

SELECTIONS.

AUDITORY VERTIGO.—The literature and current knowledge of this subject are succinctly presented by Dr. Labadie-Lagrave, in some recent articles in the *Gazette Hebdomadaire*. In a brief historical *résumé* it is shown that, although isolated cases had been reported long ago by Vieussens, and by Itard, Toynbee, and others, it was not until the laborious researches of Ménière that auditory vertigo was recognized as a distinct disease. Since then it has received full attention from numerous investigators, amongst whom may be mentioned Trousseau, who proposed the title *vertigo ab aure larva*; Duplay, who named it Ménière's disease, a name subsequently adopted by Charcot, Hillairet, Politzer, Voltolini, Knapp, Hinton, and many others. The author

insists that, although the disease derives its name from Ménière, it is not to be forgotten that it is to the experiments of Flourens that we owe a rational explanation of the dependence of the symptoms on the labyrinthine lesion.

The onset is sudden. An individual in the midst of perfect health, and without appreciable cause, is seized with confusion, headache, tinnitus, and vertigo. His gait is uncertain and stumbling; when he rises, objects seem to turn round him; he staggers as if the ground sank beneath his feet. He cannot keep his balance without support, and he executes involuntary movements which impel him in a certain direction. At the same time his hearing is affected; sometimes he can only hear certain sounds. The noises in the ears are very pronounced. He seems to hear the sound of an orchestra, ringing of bells, the rushing of a cascade, or the whistle of a locomotive. Charcot dwells on the intimate relation which exists between the sudden development of noises in the ears, or the sudden exacerbation of these noises, and the onset of the vertigo. Though tinnitus is a common accompaniment of various kinds of vertigo, its intensity and predominance from the very first are characteristic of Ménière's disease.

The face is pale, the forehead bedewed with sweat, the skin cold. Then occur nausea and vomiting, which usually indicate the termination of the attack. The patient can obtain relief only by observing absolute rest in the horizontal position. There is no affection of speech, no spasm of face or extremities. Ménière once saw spasm of the face, followed by incomplete hemiplegia (on the same side as the affected ear), which disappeared in a few days. There is never tingling, numbness, nor any sensation analogous to an aura. These symptoms pass off after a variable time, and reappear sooner or later, each attack increasing the tinnitus and deafness, until the hearing is wholly lost.

The pathological conditions which give rise to auditory vertigo are sufficiently numerous, and some of them at least can be distinguished by the symptoms. In detail they are: 1. Vertigo from traumatic irritation; 2. Vertigo from galvanic excitation; where the electrodes are applied to the mastoid processes the head turns towards the positive pole; 3. Labyrinthine vertigo from internal otitis; of this the author distinguishes three kinds; 4. Vertigo from disease of the middle ear; 5. In rare instances vertigo occurs from obstruction of the auditory meatus; 6. Reflex vertigo; in some persons the access of a drop of water to the membrana tympani brings on a violent attack of giddiness.

Taking otitis labyrinthica as the lesion which gives rise to the most characteristic symptoms, the author proceeds to treat of these latter in two groups, according to the two divisions of the auditory nerve. The vertigo, the sense of rotation or the actual rotation, with their accompaniments, staggering, weakness, pallor, sweating, nausea, vomiting, and headache, are due to lesions of the semicircular canals. On the other hand, the tinnitus, and the gradual and finally complete loss of hearing, are owing to alterations of the cochlea.

To explain the deafness for certain sounds, the author adopts the hypothesis that a limited portion of the cochlea is injured in such cases; and that, as the injured fibres no longer vibrate in response to their corresponding sounds, no impression of these sounds reaches the nervous centre.—*London Medical Record*.

PARET ON THE THERAPEUTIC ACTION OF VALERIANATE OF CAFFEINE.—Dr. Paret, in his *Thèse de Paris*, 1874, No. 464, describes this substance as a product crystallized in white flakes, having a very disagreeable odor like decayed cheese. He has administered it in the form of ten centigramme pills, of which he gives from two to three. It may also be given as a syrup

containing ten centigrammes of valerianate of caffeine. Dr. Paret comes to the conclusions: 1. That valerianate of caffeine has, in some cases, appeared to put an end to the nervous vomitings co-existent with hysteria; 2. That this medicine had given to invalids increase of a decided appetite, and a physical as well as moral strength which they had not previously possessed; 3. That the vomitings of consumptive patients had not been checked by it. It has also been tried in the sickness of pregnancy, but without favorable results. It appears that Dr. Labadie-Lagrave has twice used the syrup of valerianate of caffeine for infantile whooping-cough, and that this medicine, taken in doses of two fluidrachms per diem, produced a very marked improvement. The fits of coughing, which at first amounted to fifteen daily, fell to four, after a week's treatment.—*London Medical Record*.

GLEANINGS FROM OUR EXCHANGES.

BRONCHOCELE (*New York Medical Journal*, May, 1875).—Dr. St. John, in an article on Goitre, alludes to the difficulty, and at the same time the necessity, of distinguishing between its different varieties, and mentions the following diagnostic points:

The *follicular* variety may be known by its soft feel, by its limited extent, being confined to lobes or lobules, and (if of long standing) by softening in spots to fluctuation, and therapeutically by its susceptibility to iodine. It affects more frequently the lateral lobes.

The *fibrous* form is *hard* and nodular, but has generally been softer at an earlier stage. The *vascular* form has a soft feel, often pulsates expansively, may have aneurismal thrill, while the varicose variety may show the enlarged veins. The cystic and colloid are the largest variety, the colloid resembling the follicular, but softer, more symmetrical, of slower development, and sometimes giving crepitation, while the cystic gives fluctuation. Exploratory puncture gives albuminous fluid, and it may be unilateral.

Exophthalmic goitre is generally of medium size and symmetrical (though sometimes more of the right lobe, as receiving more directly the impulse of the heart). An essential characteristic of it is alteration of size in connection with relations to pregnancy, menstruation, or mental conditions. It is essentially vascular in nature at first; after a time its structure may change, and the gland become harder, and may even atrophy. Pregnancy will sometimes suspend all the disagreeable symptoms. The general circulatory derangements and constitutional weaknesses make the diagnosis, as a rule, quite easy.

HYSTERICAL AURA.—Professor Charcot maintains, in an article in *L'Union Médicale*, that in most of the crises of hysteria there exists an aura having its point of departure in one of the ovaries, and sometimes in both. This having been determined, it suffices, in order to suspend almost instantaneously the attack, to exercise strong pressure upon the ovary which is the seat of the aura. In a recent conference that was held at the Salpêtrière, M. Charcot showed the efficacy of this procedure in the case of a patient afflicted with hystero-epilepsy. In very many seizures he has suspended at will the attack by compressing the left ovary. The attack is resumed when pressure is removed. In order to exercise compression sufficiently long to avert entirely the attack, M. Charcot employed at the Salpêtrière a kind of tourniquet. Digital compression is made exactly as when one would compress the iliac artery. The fingers are pushed behind the pubes until the pulsation of the artery is felt beneath them.—*Boston Medical and Surgical Journal*.

ULCERATED SCIRRUS OF THE ŒSOPHAGUS (*New York Medical Journal*, May, 1875).—Dr. Merritt Bishop reports the case of a woman æt. 64, who had always enjoyed robust health, and who noticed suddenly some obstruction in the passage of food to her stomach. She had no pain; pulse and respiration normal. It was found to be utterly impossible to pass even the smallest bougie. The aliment consisted in the use of nutritive enemata. She survived for five days, suffering no pain, but having decided elevation of temperature. Autopsy revealed a perfect healthy condition of all the organs except the œsophagus. The malignant disease began at the cardiac orifice and extended up to the junction of the superior with the middle third, at which point a complete stricture was found, occasioned by adhesions. The surrounding tissues were very much hardened and thickened, pressing hard on the trachea, while the mucous lining was completely destroyed by ulceration.

MISCELLANY.

PARIS SCHOOL OF MEDICINE.—The new School of Medicine in Paris in its reconstruction gives opportunity for an enlargement rendered necessary by the constantly increasing number of the students who attend the courses of the school. To-day there are more than four thousand five hundred pupils. The plan as prepared by the architect, M. Ginain, divides the work into two sections. The first section consists of buildings designed for general studies, and for the administration. The new structures, being joined to the ancient buildings of the school, which were completed in 1786, permit of the preservation of the grand amphitheatre already existing, of the amphitheatres and laboratories of chemistry, of the halls for collections, of a vast library, of offices, and of the apartments for the dean. The second section, designed for the prosecution of practical studies, comprises the buildings of the hospital of clinics in the ancient convent of the Franciscans, and the apartments at present appropriated for pavilions for dissection. The principal divisions are a great amphitheatre for the courses of the faculty, various halls for free instruction, large physiological laboratories, a court for animals, aquariums, and apartments for practical anatomy (halls for dissection, laboratories of histology, of pathological chemistry, etc.); in addition, a museum of pathological anatomy within the ancient refectory of the Franciscans, and, finally, special laboratories for the professors, and various apartments. The entire expense of these works will be scarcely less than nine millions of francs.—*Boston Medical and Surgical Journal*.

MEDICAL DEPARTMENT OF THE UNIVERSITY OF CALIFORNIA.—In regard to the medical department of the University of California, to which attention has been called of late in discussions on medical education, we learn that the school was formerly a private affair, one of the two medical schools in San Francisco; its head man was without high standing in the profession, but possessed of a big fortune and a great reputation in the country. His aim was to perpetuate his name, and he

therefore offered his school to the University with the buildings, etc., on condition that it should be called its medical department, naming the building "Toland Hall." The regents soon found that they had received an elephant. The old faculty insisted on becoming the new one, and in it were two professors, one of whom could not write two words correctly; the other, an American, always declared he had a French diploma until some began to doubt it, and he then showed a German diploma, which ultimately proved to be counterfeit. The *San Francisco News Letter* got scent of the scandal and brought it out in its true light, writing to the German university and finding out that no one of that name (Dean) had ever graduated there, and then publishing the letters in its issue. We regret to learn also that there are men in the State and city medical societies who have no diplomas, and yet are tolerated and admired.—*Boston Medical and Surgical Journal*.

FROM the annual report of the "Allgemeine Poliklinik," in Vienna, for 1874, we find that during that year 23,560 persons (3 per cent. of the entire population) sought medical advice from the institution. The number was greatest during July, in which month the daily number of patients averaged 353, on some days mounting up to 500. Diseases of the respiratory system were the most common, after which came, in the order of their frequency, affections of the circulatory, digestive, and nervous systems, and of the skin.

SIGNOR PERUZZI, the Syndic of Florence, has given orders that 800 out of the 1000 dogs annually found straying in that city, which have for some years past been placed at the disposal of Professor Schiff, shall be killed by the police. They are to be asphyxiated instantaneously in a cell constructed for the purpose and filled with carbonic acid gas, which is being prepared in the precincts of the public slaughter-house.—*London Medical Record*.

THE *Deutsche Klinik* has ceased to exist.

NOTES AND QUERIES.

NORTHERN MEDICAL ASSOCIATION OF PHILADELPHIA.

A STATED meeting of the Northern Medical Association of Philadelphia will be held at the hall of the Northern Dispensary, 608 Fairmount Avenue, on Friday evening, June 11, at 8 o'clock.

Subject for discussion: Meningitis. To be introduced by Dr. L. B. Hall. The medical profession are cordially invited.

CHARLES CARTER,
Secretary.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM MAY 25, 1875, TO MAY 31, 1875, INCLUSIVE.

SLOAN, WILLIAM J., SURGEON.—Announced as Medical Director of the Department. G. O. 29, Department of Dakota, May 4, 1875.

KNICKERBOCKER, B., ASSISTANT-SURGEON.—The order directing him to proceed to Fort Colville, W. T., is revoked, and he is assigned to temporary duty at Fort Vancouver, W. T. S. O. 60, Department of the Columbia, May 11, 1875.

SATURDAY, JUNE 12, 1875.

ORIGINAL COMMUNICATIONS.

CASES OF PARALYSIS OF THE FIFTH CRANIAL NERVE.

BY FREDERICK P. HENRY, M.D.,

Assistant-Surgeon to the Eye and Ear Institute of Philadelphia; Physician to the Episcopal Hospital.

THE rarity of trifacial paralysis is shown by the following statistics: Among four thousand one hundred and sixty-nine cases of eye-disease treated at the Eye and Ear Institute of Philadelphia, from February 1, 1870, to February 1, 1875, were three cases of trifacial paralysis. In the Fifth Report of the New York Ophthalmic and Aural Institute, for the twenty months ending December 31, 1874, there is a record of five thousand five hundred and seventy cases of eye-disease, and among them but one case of trifacial paralysis, under the head of neuro-paralytic keratitis. In the report of Wills Ophthalmic Hospital for the year 1874, among three thousand eight hundred and nine cases of eye-disease I find no case of paralysis of the fifth cranial nerve. I have not included the ear-cases treated at two of the above-named institutions, although I might fairly do so, as in the five cases of trifacial paralysis (two occurring under my own observation, and the remainder in the practice of Prof. Noyes, of New York, and Prof. Norris, of Philadelphia) to which reference will be made in this paper the hearing on the paralyzed side was markedly impaired in all save one, in which the lesion was anterior to the Gasserian ganglion.

It is superfluous to prove, as might readily be done, that cases of trifacial paralysis are far more likely to present themselves at a dispensary for the treatment of eye- and ear-diseases than anywhere else: indeed, it is extremely probable that some of the cases are seen at more than one such institution, making their frequency apparently greater than it really is. The cases of trifacial paralysis which I have collected, although few in number, are extremely instructive, from the fact that they afford instances of lesion both behind and in front of the Gasserian ganglion.

The following case of *paralysis of the fifth and seventh cranial nerves, with impairment of muscular co-ordination*, seems to me of sufficient interest to warrant its being presented in detail to the readers of the *Medical Times*:

H. W., æt. 35, cabin steward, came to the Eye and Ear Institute on August 22, 1871, and gave the following history. Nineteen months before, he was attacked with right facial paralysis. The attack occurred during the night while he was on shore, the vessel on which he was employed being in port, and his attention was first called to it by one of his shipmates as he was going on board the next morning. It cannot be ascertained whether there was any impairment of sensation in the right half of the face at that time. Previous to the attack he had enjoyed good health, with the exception of occasional attacks of headache and vertigo.

About twenty years ago, he says, he had a bubo which suppurated and discharged, but there is no trace of a cicatrix in either groin. On each side of the neck, about four inches below the mastoid process, are two puckered cicatrices; the patient says the glands suppurated in 1858, and were lanced. The crests of the tibiae are slightly roughened. The man has three children, who are healthy, according to his account, and his wife has had one miscarriage, caused by fright. Eleven months ago (*i.e.*, before August 22, 1871) the right eye began to show signs of inflammation, and has continued in a state of subacute inflammation ever since. The cornea, in its lower half, is cloudy, and near its outer border is a small ulcer; there is neither pain nor photophobia, and the cornea and conjunctiva can be touched with the finger or probe without annoying the patient in the least. After the instillation of atropia, oblique illumination brings into view several posterior synechiæ. The lens-capsule is opaque, so that the retinal vessels, which are said to be enlarged in cases of paralysis of the fifth nerve, cannot be seen. In the right eye $V = \frac{2}{80}$; in the left eye $V = 1$.

The paralysis of the right trifacial is far from complete, but sensation is equally impaired in those regions to which its different branches are distributed.

The paralysis of the facial nerve is evident at a glance. The mouth is drawn to the left side; the uvula points to the left, and the velum is abnormally flaccid; the patient complains that it seems to "get across" his throat at times. He cannot close the right eye; the strongest effort approximates the lids to within a quarter of an inch of each other. The lids are not closely and evenly applied to the ball, as in health, and are very easily everted.

The sense of taste is decidedly impaired. I tested it by placing a small quantity of sulphate of quinia upon the right side of the tongue, and mixing it thoroughly with the saliva; the patient did not perceive it until, in the act of swallowing, it passed over the base of the tongue and impressed the nerve-filaments of the glosso-pharyngeal.

It is a question how much the loss of this special sense depends upon paralysis of the fifth, and how much upon that of the seventh, for, as is well known, in paralysis of the seventh of one side the sense of taste is impaired on the corresponding side. This is supposed to be owing to paralysis of the chorda tympani which accompanies the lingual branch of the fifth.

The sense of smell does not seem to be impaired, and the Schneiderian mucous membrane presents nothing abnormal so far as can be seen. The sense of hearing in the right ear is completely abolished. The membrana tympani is perforated, and there are signs of former inflammation of the middle ear. There is constant tinnitus. At present the patient is suffering from supra-orbital neuralgia.

What chiefly troubles him, however, is not the affection of the eye, nor the paralysis of the face, with its attendant deformity, nor the supra-orbital neuralgia, but a certain unsteadiness of gait during the day, which, after dark, amounts to staggering. This has been so great as to cause him to be suspected of drunkenness and dismissed by his employer. On closing his eyes and keeping his legs close together, he stands firmly, and can even walk a few steps with the eyes closed without staggering. He cannot walk steadily along a narrow passage without touching the wall with one of his hands, nor can he go up-stairs readily without touching the banisters. This, he declares, is not to support himself, but merely as a guide, and he says that if a cord were stretched above the stairs, he could ascend steadily by merely touching it with one finger. This was not put to the proof. In this case it would

appear that the deficiency in co-ordination is supplied by the special sense of touch, instead of by the sense of sight, as is most commonly observed. The impairment of the sense of sight may serve to account for this substitution.

The treatment consisted in faradization of the facial muscles, and the internal use of hydrarg. chlorid. corrosiv., gr. one-sixteenth, and potass. iodid., gr. x, thrice daily. The zygomatic and risorius muscles were the only ones that responded to the current, and those but feebly.

September 5.—The corneal ulcer has disappeared, and with a strong effort the lids can be approximated to within one line of each other.

September 13.—H. W. has obtained employment as cook in a restaurant, where his kitchen consists of a narrow passage about three feet by twelve, along which he moves without difficulty and without using his hands to guide himself.

My last notes of the case are dated October 27, at which time the staggering was so slight as to be of no inconvenience; the whole cornea was clear, and the man's general health greatly improved; the mouth was still twisted to the left side.

During a connection of four years with the Eye and Ear Institute I have seen but one other case similar to this. In it there was the same insensibility of the cornea and right side of the face, and a very unsteady gait. The right facial nerve was also paralyzed. There was, however, an undoubted history of syphilis. The attack came on after exposure to cold. The man was thrown out of a sleigh while on a drunken frolic, and lay in the snow the greater part of the night.

In a paper entitled "Paralysis of the Fifth Cerebral Nerve and its Effects," read before the New York Academy of Medicine (*N. Y. Med. Record*, July 15, 1871) by Prof. Henry D. Noyes, the history of two cases is given in detail. The first case occurred in a man *æt.* 33, without syphilitic taint. The fifth and seventh nerves of the right side were paralyzed, and the senses of taste, smell, and hearing much impaired. The membrana tympani was intact and transparent. There was at first occasional giddiness, which increased as the case progressed to a fatal termination. The cornea sloughed away entirely. A cancerous tumor had been removed from the lip before the patient came under the observation of Prof. Noyes; this ultimately recurred in the cicatrix, and destroyed the patient. There was no autopsy.

In Case II. the paralysis was limited to the two superior branches of the fifth, and the affection of the eye was very severe. Perforation of the cornea seemed imminent, and there was hypopion. Recovery took place under the use of electricity, atropia, and warm fomentations.

In the Transactions of the American Ophthalmological Society for 1871 is the report of a case by Prof. William F. Norris, of Philadelphia, in which there was neuro-paralytic ophthalmia of the left eye which proceeded to perforation of the cornea. There was slight paralysis of the left facial, and marked deafness of the same side, also impairment of the sense of taste. There was a large epithelioma at the left angle of the mouth. The case ran a rapid course to a fatal termination, its whole duration

occupying less than two months. At about the end of the first month dizziness and staggering occurred. There was no autopsy.

In the two cases which I have observed, the lesion was central, involving, probably, the deep origin of the fifth, the superficial origin of the seventh, and irritating or compressing the cerebellum. The affection of the eye was subacute, and, with the exception of the anæsthesia, may be, perhaps, fully accounted for by the paralysis of the orbicularis muscle. This is shown by the fact that, in the case which I have given in detail, the keratitis disappeared as this muscle regained its power, although the anæsthesia remained. In the two cases in which the lesion was probably a rapidly-growing tumor, as evidenced by their progressive nature and the appearance of epithelioma externally, the Gasserian ganglion was probably involved, and the eye-affection was very destructive. The most instructive case in this point of view is the one reported by Prof. Noyes, in which the lesion was *undoubtedly* in front of the Gasserian ganglion, as shown by the fact that the inferior branch of the nerve was unaffected, and here the eye-affection was very acute and threatening, and would have proceeded to complete destruction of the ball had not the cause of the disease been removed by treatment.

In concluding, I would call attention to the remarkable analogy between the effect of alcohol upon the nervous system and some of the symptoms presented by the above-mentioned cases. One of the earliest effects of alcohol is paralysis of the fifth pair, evidenced by numbness of the lips (Anstie, "Stimulants and Narcotics," p. 188), while it is needless to mention the unsteadiness of gait produced by that agent.

The fibres of origin of the fifth pair have been shown by anatomists to enter the cerebellum, "spreading out on the surface of its middle peduncle" (Gray's Anatomy), so that the observation of Anstie of the paralyzing action of alcohol upon the trifacial nerve lends weight to the theory that the species of locomotor ataxia produced by this drug is due to a toxæmia of the cerebellum. These considerations have induced me to attribute the disorders of muscular co-ordination which occur, so far as I know, invariably in connection with central paralysis of the fifth cranial nerve, to a lesion of the cerebellum.

INFLAMMATION AND ULCERATION OF THE APPENDIX OF THE CÆCUM, PRODUCED BY AN ORANGE-SEED, THE CAUSE OF FATAL PERITONITIS.

BY S. C. THORNTON, M.D.

ON Tuesday, June 30, 1874, I found E. C. B., 19 years of age, in bed, complaining of continued pain in the hypogastrium, which had already lasted two days.

Suspecting that he had colic, I gave him three grains of calomel and half a grain of morphia, and directed warm fomentations over the whole abdomen, and another half-grain of morphia to be exhibited in six hours if required.

The second dose of morphia was taken at 12 P.M. He rested well after it till 5 A.M., but after this the pains

became constant and more and more intense, so that at my second visit (July 1) they were unbearable. Another half-grain of morphia was given, with two large tablespoonfuls of castor oil. An hour afterwards he had an alvine passage. One-half grain of the morphia was directed to be given every four or six hours till he rested well.

Thursday, 9 A.M., I found him much worse. His pulse had been 108, but was now 140, and feeble. Skin cool, and covered with a profuse perspiration. Pain extended into the thorax. Abdomen hard and painful, but not much swollen. A terebinthinate stupe was applied over the whole abdomen, and morphia directed to be given as before.

3 P.M.—In addition to the other symptoms of yesterday, there was vomiting of bile.

11 P.M.—He was in a collapse. Directed the medicines to be discontinued.

Friday, 5 A.M., he died.

Drs. E. P. Townsend and A. W. Taylor, of Beverly, took part in the post-mortem.

The whole peritoneum—parietal and reflected—was found inflamed. In addition to the characteristic bright-red color, the apposed surfaces were firmly agglutinated by exudation. There was also in the abdomen a copious serous effusion, having a milky appearance from the large number of fibrinous flocculi in it. The peritoneum covering the convex surface of the liver was covered with coagulable lymph; that covering the stomach, mesentery, and bladder was free.

A careful examination of the appendix revealed an ulcerated opening, into which Dr. Townsend readily passed the handle of the scalpel.

In the right iliac fossa Dr. Taylor found a substance which he suspected had escaped from the gut. This, apparently, was a scybala of the size of a black-heart cherry. After washing it, Dr. Townsend and Dr. Taylor inclined to the opinion that it was a biliary calculus, but, on close examination, an orange-seed was found to be the nucleus of the mass. The appendix was only two and five-eighths inches in length, but augmented to three-fourths of an inch in thickness.

The calculus made its exit equidistant from the two extremities of the appendix. An adhesive inflammation must have followed the destroyer, for all communication between it and the cæcum was obliterated. And yet to the last it retained its fecal covering. The gall-bladder was distended, full of bile, but free from calculi.

REMARKS.—An interesting feature of this case was that during many months the patient had complained of much pain in his right hip, which was often increased by riding and sometimes relieved by walking. Was this pathognomonic of cæcitis, of inflammation of the appendix, or of both?

NOTES OF HOSPITAL PRACTICE.

CHARITY HOSPITAL, BLACKWELL'S ISLAND, NEW YORK.

CLINICAL SERVICE OF F. R. STURGIS, M.D.,

Lecturer on Venereal Diseases in the Medical Department of the University of the City of New York, etc., etc.

SYPHILITIC ECTHYMA.

GENTLEMEN,—I have three interesting cases to show you to-day of so-called syphilitic ecthyma. I shall exhibit the three together for the purpose of comparison, as they are really three different stages of the

same lesion. Before showing them, however, permit me to say a few words in regard to the nature of these lesions. In the books, you know, the pustular syphilides are divided into acne, impetigo, and ecthyma syphilitica. This is, to a certain extent, a bad nomenclature; and I would suggest, in place of it, that we adopt a name which describes the characteristics of the lesion and its cause. These lesions really begin as a pustule; and if we call them pustulo-crustaceous and pustulo-ulcerous, we describe not only the pathology of these lesions, but the cause as well.

To begin with the first case. She can assign no date for the time of the primary lesion; nor does she remember to have seen any evidence of syphilis previous to her present trouble. Nine weeks ago she noticed reddish spots appearing upon her back; these came out also on her hand; in a short time they became pustular, broke, and scabbed. For the last three weeks she has noticed that her hair came out while combing it. From the appearance of the eruption, the lesion is one which would generally be classed under the head of the tertiary rather than the secondary stage; though, as regards this point, the dividing line between these two stages is very vague and ill defined. An ecthyma may occur as an early as well as a late symptom. The correct division would be into superficial and deep,—those which appear in the early stage of the disease being superficial, the deep ones being the late lesions. You notice in this patient the different stages that the eruption goes through. Here the red discoloration of the skin becoming rapidly changed into a pustule, the pustule becomes ulcerated, and the ulcer is covered with a crust. If we remove one of these crusts, you will see that the ulcer beneath is superficial.

The rest of the lesion in this case is upon the back, the hand, and the scalp, although it is by no means confined to these localities. It may be present upon other portions of the body, but affecting chiefly the lower extremities and the back.

In the second case, on the other hand, you notice a different condition of things. The lesion is not so copious; the crust covering the ulcer is a great deal thicker, and you see that it is surrounded, in a more marked degree than in the first case, with a dusky-red border or areola, which extends for some distance beyond the crust. In stripping off this latter, you notice that it is quite tenacious; and upon exposing the ulcer beneath we find that, although superficial, it is deeper than it was in the preceding case. We have here an advanced stage of the same process, in which the first stage was a pustule; this became slightly ulcerated and covered with a soft crust; as the disease progressed, the ulcer became deeper, and the crust thicker and more adherent. We also notice that the suppuration is more abundant, and that bleeding occurs after detachment of the crust.

In this second case, the history is briefly that about four years ago she contracted a sore, followed by an enlargement of each groin, neither of which supplicated. One year following, she had a squamous eruption. Two years ago she had an ulcer on each leg; and about eight months ago, a pustular eruption, similar to the present one, came out upon her arms and legs. About March 1 she noticed reddish spots on her chin, which extended upward towards her lips. These were at first hard, but subsequently ulcerated, especially at the corners of the mouth. Three weeks ago a new eruption appeared upon her back. You notice in the history of the case that there has probably been a relapse. Earlier lesions are much more likely to relapse than the late ones, and when this occurs the symptoms often assume the same character as the preceding lesion. Let me call your attention to one point, to wit, the lapping of the sound skin over the edges of the crust. This

occurs from the ulcer extending beneath the skin farther than appears at first sight; in other words, the skin is undermined, and the secretion coagulating on exposure to the air, along the edges of the undermined skin, gives the crust the appearance of being embedded in the tissues beneath. If we examine the crust closely, we see that it is elevated above the surrounding skin, is convex, and thinner in the centre than at the edges, differing from a "rupial" crust, which is thicker at the apex than at the edges. This is due to the ulcer in the latter case being deeper and having more sharply-cut edges; whereas in "ecthyma" the ulcer is more superficial and the edges are on a higher plane than is the centre.

Let us look at the third case. Here, upon the breast, the crust is decidedly thicker and higher than in the other two; and on removing it you see that the ulcer beneath has begun to granulate. In these advanced cases the edges of the ulceration are undermined and steep, looking as though they were punched out; there is, therefore, a decided loss of tissue. The supuration here is more abundant than in the other two cases, and the crust correspondingly thicker. As these ulcerations heal, granulations (as you see) spring up from the floor of the ulcer; the sides contract, and, after a time, cicatrization is perfect. The resulting scar is of a dead white color, resembling somewhat a burn, and depressed below the surrounding skin. You see here upon the shoulders such scars left from old by-gone ulcers.

Can we draw from these cases any idea as to the character of the primary lesion which preceded? Not always; but sometimes we can. In those cases where the subsequent symptoms take on ulcerative action, we may assume that there has also been ulceration of the primary lesion. This point was investigated by M. Bassereau, a French physician, and he found that where the chancre was phagedænic the subsequent lesions were apt to assume an ulcerated character, and *vice versa*. This arises, I am inclined to believe, from the patient's condition, which, bad from the beginning, induces ulceration, not only in the chancre, but in all the other lesions.

A word with regard to the date of the appearance of these lesions. In the books, you know, they are described as being those which occur at the late stage of the disease. Undoubtedly true; at the same time these symptoms may and do occur at an early stage of the syphilis, differing from the late lesions in that the ulceration is superficial as compared with the latter. I therefore think that the more correct division would be into superficial and deep, rather than the chronological one of secondary and tertiary.

As regards the diagnosis, the history will often be of more importance than the appearance of the lesions themselves. Paradoxical as it may seem, there is nothing absolutely pathognomonic in the appearance of the lesions of syphilis whereby on inspection you will be able to say of two given lesions, this one is syphilis and that one is not. Even the peculiar copper-color which is so often insisted upon in the books as peculiar to syphilis, you will find in eruptions which have nothing to do with the disease: so that one of the main points which has been borrowed from the old writers is really of less importance than was at first supposed. There is one point, however, which is of value; and that is the greater tendency which the syphilitic eruptions have to ulcerate and break down than the non-syphilitic ones; but even on this point you must not lay too much stress. The later lesions are not only an expression of disease being still present, but they are usually associated with a vitiated condition of the system. You notice the difference in the physical appearance of the three women. In the first case the woman looked ruddy and strong. In the second case the difference between

her and the first was marked: she looked pale and weak; while in the third the difference was still more marked: she had a wan, cachectic look. The difficulty is not so much in curing the lesions as in getting the patients up to their former condition. The disease is from the very commencement constitutional; is one that taxes the energies of the patient from beginning to end; *serious, from what it may result in, for, however superficial the primary lesion may be, you cannot tell absolutely whether tertiary lesions will not supervene.* It is very necessary, therefore, to treat your patient well from the start; to prevent, if possible, the appearance of late lesions.

In respect to the treatment, it is twofold,—specific and tonic. By specific treatment is meant treatment with mercury and iodide of potassium. Of late years there have been quite warm discussions as to the relative value of these two remedies, some contending that mercury, if not actually injurious, is at least inferior to the iodide. This I believe to be a mistake; and the profession at large are coming to regard mercury as the safer and surer agent in the treatment of syphilis. You must not, however, limit yourself to any special mode of treatment, but adopt that which appears most fitted to the case in hand.

Let us study the treatment of these late lesions. It is in these cases that the iodide of potassium has been especially extolled, and not without reason; it is undoubtedly of benefit. But you will often find that after the iodide of potassium has been given for some time the symptoms will not improve beyond a certain point, but will remain stationary. If, now, mercury be added to the treatment, the patient gets well. I have therefore come to regard the iodide of potassium in these cases as the adjunct, and not as the main agent in the treatment. There are two methods of giving mercury,—externally and internally. Of these two, much may be said for the external method. One reason why it has not been so much used in this country, particularly in private practice, is that patients object to the soiling of their linen; but that may be obviated by using the same underclothes while the treatment is going on. It has the advantage of leaving the stomach entirely free, and the less that is disturbed with medicine the better. In these cases you must remember to build your patient up; reserve the stomach for food, and the skin for the specific treatment. It is surprising to see how the mercury will be absorbed, if the inunction is properly administered. Remember that in these lesions you have a serious condition of things. Ulceration, sometimes deep, is present; this, perhaps, extends; the disease progresses; important organs are threatened; the bones and viscera are attacked, and when this happens it very often becomes a nearly hopeless affair. Suppose the alimentary canal is attacked; of course your patient will not assimilate his food; tonics are of little use, and, push your treatment as far as you please, your patient will not recover; he falls into a condition of marasmus, and perhaps dies. Fortunately, however, few cases go so far as this. A great deal of the bad name that mercury has received is due to its improper use; and many practitioners, uncertain of its action and fearful of doing harm, give it in a very hesitating and doubtful manner. If you are going to give it in that way you had better not give it at all; much better depend upon the iodide of potassium. If you give mercury, give it in full doses, and, where occasion requires, freely. It is surprising to see how much mercury your patient will tolerate. Rub in half a drachm of the ointment to begin with, and increase it up to one or two drachms, if the patient will stand the dose. You will then find that the lesion will go away, where a smaller quantity would have no effect. Although I advise you to be bold in your treatment, I do not intend you to be

rash. Watch your patient; observe the effect of the treatment; see if the lesions disappear; and should any untoward symptoms, such as salivation, stomatitis, or diarrhoea, supervene, suspend the use of the mercury at once. There are various other methods for its external use,—viz., by baths, fumigation, and hypodermic injection. They present no special advantages over inunction, and many disadvantages; so that, although useful in some cases, they do not need more than a passing notice here.

Internal treatment is principally with the bichloride of mercury, the protiodide of mercury, and blue mass, with or without tonics; and of these the former is the one most frequently used. Many who use it speak well of it. Personally, I am sorry to say, I cannot do so. In my hands I have found it is liable to produce the toxic effects speedily, and is not capable of being pushed to any great extent. One of my favorite ways of giving mercury by the mouth is to use the blue pill (*massa hydrargyri*) in connection with quinine or iron. The formula I use is two grains of the mercurial to one grain of the tonic, in pill form; one, two, or three to be given three times daily, p. r. n. In this way of giving it the mineral is rapidly absorbed, and very seldom disturbs either the mouth or the bowels. This I give more especially in the early stages of the disease. I wish to direct your attention for a moment to the use of the quinine and iron. From the commencement, in the early as well as in the late stages, the red blood-corpuscles are notably altered in number and quality. From the very beginning, syphilis is a blood-disease, so that a tonic, in addition to the specific treatment, becomes an essential. Do not, because you know the value of mercury and iodine in the treatment of syphilis, underrate the advantage to be derived from the use of tonics. You must always bear in mind that the patient is to be sustained in general health and strength, as well as cured of his syphilis.

Another preparation of frequent use is the protiodide of mercury, given alone, or combined with conium or opium. The usual dose is from one-half grain to one grain, daily, either in a single or divided dose. It is usually given in conjunction with the iodide of potassium, under the name of the mixed treatment. With regard to the iodide of potassium, the same rule is to be followed as in the administration of mercury,—give it freely. The great mistake that nine practitioners in ten make, is to give a dose of iodide of potassium in from three to five grains. This is too little; the patient will stand the iodide well; his disease very often imperatively requires it. Begin, therefore, with ten grains, and from that run it up until your patient cannot stand any more, or until the symptoms yield. The moment that occurs, stop the remedy. It sounds like an enormous dose, but in this hospital I have run patients up to over five hundred grains a day, with the effect of relieving their symptoms, when with less no result was obtained. Thus, you see, this remedy can be pushed to a great extent; and if, in the deep lesions of the bones and other organs, you give only a small dose of ten or twenty grains, the disease, so to speak, laughs at it. Give a dose of forty grains or more, and the symptoms vanish. Be cautious, then, with whatever drug you use; do not give it rashly, but do not hesitate to employ it freely.

With regard to tonic treatment, you must remember that in these late cases there is very decidedly-marked cachexia, and that it must be your duty to overcome, so far as possible. Build up your patient, then, with good food, stimulants, and tonics. The mercury will second the action of the tonic,—indeed, will itself act as a tonic.

TRANSLATIONS.

DIAGNOSIS AND TREATMENT OF NEURALGIAS.—Pitha (*Allgem. Wien. Med. Zeitung*, No. 1, 1875, et seq.), who has himself been a victim of various neuralgic symptoms following purulent infection, gives some curious experiences relative to his various subjective symptoms.

Neuralgia of the base of the bladder gave the impression of a calculus; the sharp projections could be felt against the mucous membrane, and on movement the stone was perceived to strike against the pubic symphysis. Examination by means of a sound showed the absence of any calculus, and the characteristic symptoms disappeared gradually from this time.

Neuralgia of the heel gave the impression of a subperiosteal separation of bone; instruments scraping and operating in this locality were also felt, though no bone-trouble was present.

The various forms of neuralgia from which Pitha suffered seemed central in their origin, and defied all therapeutics.

He has therefore had recourse to injections of morphia, which method of using the drug seems the most desirable. He suggests that the remedy should at first be used in the smallest doses; these not to be given in rapid succession, and only gradually to be increased, since the narcotic effect is cumulative.

Certain individuals, particularly those suffering from cardiac weakness, have such an idiosyncrasy against morphia that even the smallest doses are sufficient to bring on the most marked toxic symptoms,—deathly pallor, cold sweats, intermission of the pulse and respiration, protracted nausea, and vomiting. Chloroform and chloral hydrate seem to act similarly on such persons; the author therefore urges the greatest caution in giving the first dose, and also as regards avoidance of veins.

In case of poisoning, he counsels fresh air, affusion with vinegar and cold water, enemata of strong coffee, and, if necessary, artificial respiration. If the symptoms persist, Pitha suggests the trial of chloroform inhalations. Against the disagreeable effects of morphia on the intestinal canal, Pitha suggests the use of muriate of quinia in coffee, and occasionally one one-hundredth grain injection of sulph. atropia. By long use of morphia these symptoms disappear, as does also the persistent but not disagreeable sleeplessness. He has never observed any evil psychical effect from these injections. The injection should not be made near the affected part. Pitha has devised an instrument for painless injections in which the fine needle-point is suddenly thrust under the skin by a spring. Patients should never be trusted with hypodermic syringes.—*Centralblatt*, No. 18, 1875. X.

CONGENITAL LUXATION OF THE KNEE.—Dr. Dubrisay reports the following case (*Le Mouvement Médical*, May 8). A healthy young woman fell into labor at full term, the infant presenting by the head, and the delivery being accomplished without difficulty. After cutting the cord the child was examined, and it was found that the right femoro-tibial articulation presented a vice of conformation. The right leg, by a double movement of forced extension and internal rotation, had been twisted forward in front of the thigh and abdominal walls, the extremity of the right foot being in contact with the right flank. The limb was restored without difficulty by simple extension and flexion; the movement of flexion was easy and normal when made either by the volition of the child or artificially, but when the limb was left to itself, if the child restored it by extension it did not remain in a straight line, and the displacement was reproduced, the leg forming a right angle with the thigh. None of these movements

seemed to give the least pain. A gutta-percha apparatus was applied so as to keep the leg partially flexed, and this was re-arranged morning and evening. At the end of five weeks a complete and permanent cure was attained. X.

HEMORRHAGIC PLEURISY.—At a recent meeting of the Société de Biologie (*Le Mouvement Médical*, May 15), M. Prévost communicated the notes on the following case of pleurisy which he had observed in his clinic. A man was admitted to the ward in December, apparently intoxicated; the liver was much enlarged. Some days afterwards the right side became painful, and there was dyspnoea. Finally, all the symptoms of pleuritic effusion were noted, and thoracentesis was practised. The liquid obtained consisted in great part of nearly pure blood.

A second puncture made some days later gave exit to three litres of the same liquid. Soon after, the patient was attacked by fits of coughing, accompanied by albuminous expectoration, pointing to œdema of the lung.

The patient finally succumbed. Post-mortem examination showed large quantities of false membranes, and on a level with the first puncture a tumor was observed, which proved to be a sarcoma. This sarcoma had been developed under the influence of the traumatism produced by the various punctures. X.

ERGOT IN THE TREATMENT OF INCREASED MAMMARY SECRETION AND INFLAMMATION OF THE BREAST (J. Schtscherbinkoff: *Centralblatt für Chirurgie*, No. 19, 1875).—During an epidemic of raphania in the Russian department of Simbirsk, Dr. S. made the interesting observation that a diminution, or even an entire cessation, of the secretion of milk in nursing women was not of rare occurrence when symptoms of ergotism appeared.

He observed a similar phenomenon among cows fed with meal containing ergot, or allowed access to straw in the ears of which grains remained which had undergone similar changes. Since an accumulation of milk in the glandular parts of the breast is regarded as the chief cause of mastitis, he administered ergot in many cases in which this process was in an early stage.

In two cases of multiparæ, who at each confinement had suffered with mastitis, going on to suppuration, *secale cornutum* was administered as soon as any enlargement of the gland, due to an accumulation of milk, was noticed; and its administration was followed by the happiest results. *Secale cornutum*, in conjunction with quinine (ãã gr. v, t. d.), was also used in cases of so-called milk-fever. The same treatment which was used successfully in mammary trouble during the puerperal state was attended with equally good results in tumefaction of the gland, with febrile reaction, in women at a later period of lactation. *Secale cornutum* was also given at the time of weaning the children, in cases in which a speedy cessation of the secretion was desired. In such cases it was given up to the amount of one drachm for a week, with no unpleasant results. W. A.

PUNCTURE OF THE BLADDER.—Deneffe and Van Wetter, in a recently published work ("De la Ponction de la Vessie"), have endeavored to ascertain whether this operation is one which should only be resorted to as a last expedient, or whether it is sufficiently safe to allow of its frequent practice. Out of 328 cases examined with this end in view, 44, or 13 per cent., were found to have terminated fatally. Most of these patients, however, died from other causes; so that the operation itself could not be said to have ended fatally in more than 7 cases, or 2 per cent. of the number. The puncture was performed as follows: through the perineum (17 cured, 3 died), through the rectum (86 cured, 11 died), through the symphysis (1 case, cured), below the symphysis (1 case, cured), through the hypogastrium

(125 cured, 27 died), and, finally, by aspiration (54 cured, 3 died).

The operations of forced catheterism, external urethrotomy, and, indeed, the attempt at catheterism, are condemned as much more dangerous than puncture. Puncture through the rectum the authors regard as a very undesirable operation, and accompanied by subsequent inconveniences if the canula has to be retained.

The authors regard puncture of the bladder as more than a merely palliative measure, asserting that it has a direct influence in cases of stricture, so that a large catheter may frequently be introduced after the bladder has been emptied by the puncture. In inflammatory or traumatic strictures, the influence of puncture on the condition of the urethra is still more marked.

In difficult cases, where restitution of the normal canal can only be attained by external urethrotomy, retro-urethral catheterism through the fistula, by Verguin's method, may be employed, in order to fix the locality of the posterior section of the wounded urethra. Nine cases are cited by the authors in which this procedure was adopted successfully. Experience has shown that the peritoneum can always be avoided if puncture is made at a point not more than one and two-thirds inches above the symphysis pubis.

Capillary puncture is only recommended when there is a prospect of the urethra soon regaining its permeability. They cite two cases in which capillary puncture was performed more than twenty times in the same individual without any disagreeable result.—*Centralblatt für Chirurgie*, No. 35, 1874. X.

CASE OF MÉNIÈRE'S DISEASE.—M. Raymond stated at a recent meeting of the Société de Biologie (*Le Mouvement Médical*, May 15) that there was at that time under the care of M. Charcot a woman presenting all the symptoms found in the affection known as Ménière's disease. The least movement made in the ward caused the patient to become attacked by nausea and vomiting. She experienced at the same time singing in the ears, and vertigo. M. Charcot had ordered this patient sulphate of quinine to the extent of fifteen grains daily, and under the influence of this medication the symptoms had diminished. The constant ringing in the ear, which was almost insupportable, and which she compared to the noise of a railroad-train, had diminished in intensity, and had been replaced by a less severe ringing sensation, similar to that brought on by the use of quinine. X.

UMBILICAL TUMOR COMPOSED OF THREE HERNIÆ.—M. Lucas Championnière recently communicated the following observations to the Société de Chirurgie:

A patient upon admittance to the hospital presented all the symptoms of intestinal strangulation. The umbilical region was the seat of an enormous tumor. Death followed soon after the operation, which was performed *in extremis*. The existence of three herniæ was subsequently ascertained; one of these was situated at the umbilical ring, and the two others, constituted by an enormous mass of omentum and a portion of the small intestine, were found under the linea alba. X.

THE SO-CALLED THIRD DENTITION.—Jos. Scheff (*Wien. Med. Presse*, 1874, No. 47) notes eighteen cases in which the so-called third dentition was dependent upon the retention of one or more milk-teeth in the jaw. Some years later, eruption of these abnormally-retained teeth took place. The permanent teeth, which had remained in the jaw meanwhile, then first made their appearance. If the fact that the earlier set were milk-teeth had been overlooked, it would be easy to regard this last eruption as a third dentition. That this latter was the case Scheff denies.—*Centralblatt*, March 13. X.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JUNE 12, 1875.

EDITORIAL.

THE MEDICAL PROFESSION AT THE ANTIPODES.

ACCORDING to the *Melbourne Medical Record*, to be a doctor in that part of the world, where man walks with his head downwards, the laughing jackass is a bird, cherries have their stones on the outside, beasts have bills, and leaves are set with their edges to the sky, is to do otherwise than sleep upon a bed of roses, to be clothed with a majestic dignity, or to be the recipient of a steady flow of wealth. Including the whole population in Victoria, the doctors are about one in a thousand; and of the possible clients, nearly one-fourth depend upon hospitals and dispensaries for medical advice and treatment, and as many more belong to clubs. As the "highest medical authority of Victoria"—even the august Vice-Chancellor of the Melbourne University—"will finger a club-patient's pulse for sixpence," the outlook for new-comers is not very enticing. Yet European practitioners are notified in the advertising columns of the journal that if they wish to settle in Australia the editor will give them all "the information they may require." We should think the editorial column was a sufficient light-house.

Advertising and puffing in the newspapers appears to be with the profession in Victoria a favorite means of occupying leisure moments, and it is very clearly intimated that custom sanctions "forty per cent. from the druggists and a percentage from the undertakers." A medical profession, like wine,

requires age to ripen, and in a new country must always be composed of a mongrel set, bound together only by the loosest of ties. In 1975, we doubt not, wealth and dignity will be as closely associated with the practice of physic in Melbourne as they now are in London.

VIVISECTION IN THE ENGLISH PARLIAMENT.

TWO bills for the regulation of vivisection are now before the English Parliament. One, Lord Hartismere's bill, prohibits vivisection except in a registered place, which is to be open at any time to the visits of an inspector of anatomy. Vivisections are to be performed only on animals completely under the influence of anæsthetics, and curare is expressly excluded from being deemed an anæsthetic. The performance of a vivisection without anæsthetics requires that a special license be procured at a cost of £10, such license being terminable at the end of six months. Power is given to a justice of the peace to issue search-warrants and to prosecute, and severe penalties are attached.

The other bill is, we believe, fathered by Dr. Lyon Playfair. By it any person—for the purpose of new scientific discovery—is permitted to make an experiment on a live animal, provided the animal be rendered insensible, and be killed on the termination of the experiment, if it have been much injured. Licensed persons may subject an animal to an experiment without the use of anæsthetics, provided that the experiment be solely for the purpose of new scientific discovery, and that insensibility would frustrate the object of the experiment. A register of all such experiments is to be kept. A license may be obtained on application by any person, if accompanied by a certain certificate intended to guard against abuse; but in the case of professors of physiology, medicine, anatomy, or surgery, the certificate is dispensed with. Various penalties are attached, and the mode of their collection prescribed.

THE Legislature of Connecticut, some two years ago, appropriated five thousand dollars, and the city of Hartford a like sum, for the purpose of erecting a monument to the memory of Horace Wells, the discoverer of anæsthesia. Under the direction of a committee, a colossal statue in bronze of Dr. Wells has been executed by Truman H. Bartlett, Esq., and will soon be ready for erection on some commanding site in the beautiful park in the city of Hartford, where the discoverer lived.

It is upon the pedestal, which should be also of bronze, and its ornamentation, that any further funds ought to be expended. This will admit of high and costly adornment, in bas-reliefs, in inscriptions, etc., suited to exemplify the uses of the discovery, at the same time that it commemorates the discoverer. In order to obtain these funds, an appeal has been made especially to physicians and dentists for subscriptions. It appears to us that as it is the people who receive the great benefit of Dr. Wells's discovery, they should furnish the means to do him honor. We trust, however, that the Philadelphia profession will not be backward in the matter.

Letters of inquiry may be addressed to Dr. E. K. Hunt, Chairman of the Committee of the Hartford Medical Society. Subscriptions may be forwarded to Dr. G. W. Russell, Treasurer, Hartford, Conn.

THE celebrated natural philosopher, Pasteur, retires from his position as Professor in l'École de Médecine, owing to age. The Academy of Medicine has declared him "national laureate," and the national assembly voted him an annuity of nearly \$2500, to which should be added his retiring annuity of about half that sum; so that, loaded with honors and furnished with pecuniary means, he can enjoy his old age. In America, distinguished scientists in old age are turned out like old horses, to pick up what they can. Is it a wonder trade and commerce swallow up so much of the brain of the country, and that even men of the strongest scientific instincts are swept into a "practical life"?

At a meeting of the Board of Regents of Michigan University, it was resolved to create a homœopathic medical college, and to appoint two professors, who shall be designated respectively Professor of Materia Medica and Therapeutics, and Professor of the Theory and Practice of Medicine. For the other branches the students are to depend upon the lectures in the old medical department.

FRANK BUCKLAND, the naturalist, reasons thus: sleeplessness is often due to too much blood in the brain; eat a hard-boiled egg, draw off blood to the stomach, and go to sleep.

THE Jefferson Medical College has bought, we understand, ground back of their present edifice upon which to erect a hospital that shall communicate directly with the college building.

THE University Hospital receives \$10,000 by will of the late Mr. Towne.

LEADING ARTICLES.

SALICYLIC ACID.

NO. II.

A LEADING article published in the *Medical Times*, March 13, contains a short account of the discovery by Kolbe of a cheap method of manufacturing salicylic acid, together with a description of its chemical and physiological properties, and an allusion to some of its possible therapeutic uses.

Since it was written, a number of investigators have taken up the subject, and various communications have been published, particularly in the German journals, giving the results of experiment upon the internal and external use of the remedy in various cases. It is our intention in this article to give a brief account of the results attained, with the hope of stimulating further and more active research on this side of the water.

Experiments upon the internal and hypodermic use of salicylic acid have been made by Dr. Paul Fürbinger.* In the normal condition no lowering of temperature was observed after its administration.

Experiments in septic fever were then made, the fever being excited in animals by giving them quantities of contused spleen infused in stale urine. Salicylic acid was then administered in doses varying from .05 to 0.2 gramme, larger doses being found to produce toxic effects. Irritative fever was also produced by the inunction of croton oil, and purulent fever by means of a saline mixture containing laudable pus injected into the connective tissue.

In all these experiments the acid, when administered, was found to have marked antipyretic powers, the temperature falling very perceptibly in a period of time varying from two to six hours subsequent to its administration. In one case where toxic effects had been produced in a rabbit from an over-dose, the symptoms were those of collapse, and the post-mortem examination showed the cause of death to have been diffuse peritonitis, brought on by extensive corrosion of the lower bowel.

Dr. E. Butt† has employed salicylic acid in various cases of typhoid fever, erysipelas, and acute articular rheumatism with very good results; but the number of patients under his observation has been too small to allow great weight to be attached to his results. He believes salicylic acid to exercise a marked antipyretic effect, and is even inclined to place it on a level with quinine in this respect. No disagreeable effects have been noticed by him in any case.

Stephanides‡ has employed salicylic acid in dysentery and chronic diarrhœa. His experiments extend to only a few cases, in which, however, striking results were obtained. He administered the acid either pure "on the point of a knife" (a method, according to Kolbe,

* Centralblatt f. Med. Wissen., No. 18, 1875.

† Ibid.

‡ Wien. Med. Presse, No. 14, 1875.

not without risk), with tinct. opii, or in some cases by enema to the extent of a gramme at one time.

In a series of papers on the subject of the various organic disinfectants, Drs. Vajda and Heymann* discuss, among others, the action of salicylic acid. Its disinfectant effect they say might have been anticipated from its chemical relation to carbolic acid, but its superiority to this agent in many respects is surprising.

While the continued use of carbolic acid brings on such local symptoms of reaction as burning sensations, rise of temperature, and redness, none of these symptoms were produced by the use of salicylic acid under precisely similar circumstances. Even in a case where the cavity of a large abscess had been repeatedly washed out with a two-and-a-half per cent. solution of salicylic acid, much of the fluid necessarily remaining in the cavity, no disagreeable effects were produced. Neither have any of those general unpleasant symptoms been noticed, such as headache, feverishness, and the like, which are observed after long-continued use of carbolic acid. In dressing large superficial wounds with salicylic acid no unpleasant general effects have been observed, although the fact of its absorption is shown by a green coloration of the urine. In markedly infecting wounds salicylic acid is useless, while carbolic acid and its congener cresylic acid neutralize their effect. This is probably due to the cauterizing influence of these latter agents, since when they are used in a diluted condition they likewise are found to fail.

The most complete contribution to our knowledge of the uses of salicylic acid in surgery has been made by Thiersch.† He finds that granulating wounds upon which a solution of one part to three hundred has been sprinkled show no signs of inflammatory reaction; if after the acid has remained in contact with the granulations for some time these become covered with a white film of precipitated albumen, the healing process still goes on as usual underneath. Sprinkled upon gangrenous or other foul surfaces in substance, salicylic acid deprives them of odor, and by occasional renewal the deodorization may be maintained indefinitely. When, however, there is a thick body of putrefying tissue, the acid cannot of course penetrate deeply enough to insure the absence of all smell.

Thiersch is an enthusiastic advocate of Lister's method of dressing wounds, and his accurate and thorough manner of carrying out the plans of the latter are well known. He has, of course, used salicylic acid by Lister's method, and is disposed to give it decidedly the preference over carbolic acid. For one purpose, however, it cannot be used, that is, for disinfecting surgical instruments, since it oxidizes steel with great rapidity.

Thiersch has devised a salicylic wadding for hermetically sealing wounds treated by the antiseptic method; it is composed as follows: Two ounces of salicylic acid are dissolved in two pints of alcohol of specific gravity .83, and this solution is diluted with twenty pints of

water at a temperature of 158° to 178° F. Six pounds and eight ounces of "cotton batting," after having been first deprived entirely of oily matter, are saturated with this solution.

When dried, this wadding contains about three per cent. of salicylic acid, which is sufficient for most cases. Thiersch employs, however, another wadding containing ten per cent. of the acid, and which he distinguishes from the first by tinting it slightly by means of cochineal. When handled dry, this wadding should irritate the hands slightly; if it does not do this, it does not contain a sufficiency of acid.

The cotton wadding thus used by Thiersch has one disadvantage, it is slightly less permeable than it should be, and therefore, in cases where the discharges are abundant, these are apt to form collections under the dressing instead of soaking into it. To avoid this, Thiersch uses jute impregnated with salicylic acid in profusely suppurating wounds. This, though coarser than cotton, is much more permeable.

Thiersch's experience extends to one hundred and sixty of all kinds of surgical cases, treated in the Leipsic clinic during the past year. He finds that under the use of the salicylic acid, cases of pyæmia were much diminished. Erysipelas, on the contrary, did not appear to be affected. In thirteen cases, one fatal occurred.

This circumstance suggests a curious dilemma commented upon by Thiersch. If Lister's method excludes the atmospheric ferment, then erysipelas cannot be due to this cause. If, on the other hand, erysipelas is due to this cause, then Lister's method is powerless to prevent the access of germs to the wound.

Thiersch inclines to the former view, and regards the bacteria found in erysipelas, even under Lister's dressing, as of accidental occurrence.

A discussion, however brief, on the subject of the relation of vegetable organisms to disease, would lead us far out of the range of a short article like this, whose object is entirely practical. We will, therefore, avoid this, and in conclusion state a few of the advantages and disadvantages claimed for salicylic acid.

1. It is antiseptic.
2. It is odorless. This is a double advantage, for not only does it make the application of the remedy much more agreeable, but the limit of its effect can easily be measured when it is used in foul-smelling discharges, and the amount to be employed may be regulated accordingly.
3. It is non-irritating when applied to the skin, to wounds, or to granulating surfaces.
4. It is not poisonous when absorbed into the circulation.

On the other hand, salicylic acid must be admitted to have certain inconveniences. Like carbolic acid, it roughens the hands if they are much exposed to the vapor, as in Lister's method of dressing; and it also excites coughing and sneezing when inhaled, until toleration is induced. Doubtless other inconveniences may appear when further investigation is made, as it is usual

* Wiener Med. Presse, Nos. 6-19, 1875.

† Volkman's Sammlung Klinische Vorträge, Nos. 84 and 85, 1875.

for a new remedy of this sort to put its best foot foremost; but enough has been done to induce a full and thorough trial in hospitals and by physicians generally. In this city, Dr. Washington Atlee has recently used a strong solution of salicylic acid for the purpose of washing out the abdominal cavity after the operation of ovariectomy. No signs whatever of any local irritation were observed, but the patient succumbed a few days after the operation from an immediate suppression of urine. As the post-mortem examination is said to have revealed renal disease of some standing, it is impossible to say whether or not the salicylic acid could have had any injurious effect in this instance.

Dr. A. Hewson has cured a case of favus, without cutting the hair, by two applications of a saturated solution of the drug. We believe also that our surgeons are using it with satisfaction. X.

CORRESPONDENCE.

THE NEW JERSEY STATE MEDICAL SOCIETY.

ATLANTIC CITY, May 26, 1875.

MR. EDITOR,—Our city by the sea recently had a regular spring tide of doctors, and, thinking it would perhaps keep bright for a season your fireside, I have gathered up some drift-wood. We do not enjoy the inestimable advantage of a county medical society, and consequently the Camden Society made all the arrangements and did the honors of the occasion. With the aid of the Camden and Atlantic Railroad president, they whirled us from your city through the delightful scenery of Jersey,—concerning parts of which your correspondent could well believe what tradition states, *i.e.*, that the crows weep for pity as they fly over it. If every tear-drop crystallized into a grain of sand, crows must have been abundant. At Congress Hall we found the tables loaded with Jersey wine,—a present from one of the neighboring vineyards. Talk not of Heidelberg, when Atlantic City is at your doors. Rather thin, and smacking of the vinegar-cask, however.

In the evening the serious business commenced. At the appointed hour the 109th meeting of the New Jersey State Medical Society was called to order by Dr. Larison, of Hunterdon County, the President of the Society. Eighty-seven delegates, representing eighteen counties, responded to their names at roll-call. There were also delegates present from the New York, Pennsylvania, Massachusetts, and Rhode Island medical societies.

Dr. John W. Snowdon, of Camden County, chairman of the committee, welcomed the Society to Atlantic City in an interesting address, in which he detailed some of the peculiarities and hygienic advantages of that seaboard section of the State, in which he has practised upwards of thirty years.

Dr. George H. Larison, the President, then read his address. He spoke of the progress of New Jersey during the past century, and alluded to the approaching

centennial celebration of the nation. He then traced the development of the science of medicine from the time of Moses down to the present day, and closed with a very fine peroration, referring to the duties of physicians, both as individuals and as associations.

Dr. Wickes, from the Standing Committee, reported that the records of the Society were complete for one hundred years past, and a committee was appointed to revise and publish them.

At this point occurred what is unusual of late years, but what was very customary in the earlier history of the Society: two candidates applied to the Society for examination for the title of M.D., which, according to the laws of New Jersey, enables them, if they successfully pass it, to practise in that State without a college diploma. Drs. Kipp, of Newark, Foreman, of Hudson, and Newell, of Hunterdon, were appointed a committee to examine them. If this examination, which these two gentlemen successfully passed, was as thorough (and we do not doubt that it was) as in the old days, when the law compelled every doctor who wished to practise in New Jersey, whether a graduate of a medical college or not, to pass an examination before the State Society, they may be proud of their success; for I have a vivid recollection of hearing some of the Nestors of the profession in that State recount how they had passed through both an examination at college and at the hands of the Society's Committee, and that the latter was much the more trying ordeal. I could not help thinking what a change would take place if that old law could be re-enacted,—how the State would be cleared of quacks and charlatans, and what—tell it not in Gath—a consternation would prevail in the very ranks of the Society.

The Nominating Committee was then appointed, consisting of one delegate from each county represented in the Society, who sit after the adjournment of the evening meeting, and select the officers for the succeeding year, and also name the place at which the next meeting will be held.

In the evening the Camden County Medical Society gave a banquet to the assembled doctors, followed by the usual round of speeches. Your correspondent was clearly established in his belief that doctors are men of deeds, not words, but was mightily shaken by the witty speech of Dr. Hunt, and well pleased by that of Mr. Lucas, a railroad director, who proved conclusively that to enable a baby to digest his nursing-bottle, india-rubber teat and all, it was only necessary to bring him to Atlantic City.

After the opening of the regular meeting of Wednesday morning came the report of the Standing Committee, read by the chairman. This is the most interesting report made to the Society, and is a feature peculiar to this Association; and, I believe, has no parallel in any other medical organization in the country.

The Standing Committee of the New Jersey Medical Society is composed of three members, two of whom are elected annually, but the chairman is a perma-

nent officer. This position is now, and has been for many years, filled by Dr. Stephen Wickes, of Essex, certainly one of the ablest men in the Society. It is the duty of this committee to obtain reports from all parts of the State,—reports from district medical societies of the meteorological and sanitary condition of their sections, the diseases prevailing during each year, their treatment, reports of specially interesting and unusual cases,—in fact, a report of everything that can interest the profession; and all communications upon these subjects must first pass into their hands before they can be presented to the Society. Annually it is their duty to compile from the documents received from all these various sources a general report, to be read at the yearly meeting of the Society, which gives as it were a panoramic view of the medical history of the State during the previous year.

The local reports themselves are not read unless deemed by the committee exceptionally interesting. They are, however, published with the transactions of the Society, and distributed to every member of it. No discussion of this report has heretofore been allowed, but during the morning, on motion of Dr. E. M. Hunt, it was adopted that at future meetings a discussion of half an hour should be permitted, limiting each speaker to five minutes' time. By the above plan the duration of the annual meetings has been accurately limited to one evening and one day, and yet all the affairs of the Association are thoroughly attended to.

From the report of this year, read by Dr. Wickes, we learn that the health of the people of New Jersey has been unusually good during the past year; but few local epidemics were reported, and among them was one of births from Cape May County. Last summer and autumn were exceptional healthy seasons; cholera morbus, cholera infantum, dysentery, and diarrhoea being milder and less frequent than usual. The valleys of the Delaware, Raritan, and Passaic Rivers, where malarial diseases are common, enjoyed unusual exemption from them. The severe cold weather of the winter and early spring caused an increase of sickness, and pneumonia, scarlet fever, diphtheria, and other throat and thoracic affections prevailed throughout most of the State. Diphtheria occurred endemically over many districts, and was frequently fatal. One reporter remarks that in his district it was chiefly confined to low and unwholesome localities, but reports two instances in which it occurred in places enjoying the best hygienic advantages, where, upon investigation, he found unnoticed sources of poison from organic matter. Another reporter narrates a very singular circumstance. During the last summer, three children were sent from one of the cities in East Jersey to a farm in the country to preserve their health, which was good. They were given milk to drink from one fine, healthy cow. One day the cow escaped from her pasture-field into an adjoining one, containing the same kind of pasturage, and also a pond of stagnant water from which she drank. The next day one of the children was taken suddenly sick, and died; and, within a few

days, the other two were also taken sick, and died. The cow remained perfectly healthy.

Dr. William Pepper, of Philadelphia, being favorably reported from committee by Dr. Bodine, of Trenton, was unanimously elected an honorary member of the Society.

Dr. Elmer, of Trenton, Corresponding Secretary, made a report of his correspondence with other societies, etc., during the year. He also reported that at the last session of the Legislature a bill was introduced into the House by the homœopaths, appointing a Board for the Granting of Licenses, to be composed of four regular physicians and three homœopaths. This was defeated in the Senate by the vigilance of the Trenton doctors. The bill for the organization of a Board for the Regulation of the Sanitary Condition of the State had been defeated. This subject afterwards gave rise to a considerable debate, as the policy of the State Society has been for many years to have as little legislation in their behalf as possible, deeming it the wisest course to ask only for what was indispensable to them, and to prevent quackery from getting anything. The whole subject was finally referred to a committee.

After various reports, essays, and resolutions had been read or acted upon, Dr. Pumyea, of the Nominating Committee, reported the following officers for the ensuing year: President, Dr. William O. Gorman, Newark; First Vice-President, Dr. John V. Schenck, Camden; Second Vice-President, Dr. H. R. Baldwin, Middlesex; Third Vice-President, Dr. John S. Cook, Warren; Recording Secretary, Dr. William Pierson, Jr., Orange; Corresponding Secretary, Dr. William Elmer, Trenton; Treasurer, Dr. W. W. L. Phillips, Trenton; Standing Committee, Drs. S. Wickes, S. Thornton, and Thomas Ryerson. These officers were unanimously elected.

Cape May was adopted as the place of meeting in 1876. SAND CLAM.

NEW YORK, May 24, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

THE "Baldwin Pavilion" of the Woman's Hospital is now almost completed, but it cannot be opened for some time, unless some of the friends of the institution will endow it still more liberally.

It seems that Mr. John C. Baldwin gave a hundred thousand dollars for this building, on condition that it should be erected within a certain specified time. The income of the hospital now, however, will not permit of the increased expenditure necessary for the maintenance of this addition, and the new portion will, therefore, probably have to remain unoccupied for the present. This is the more to be regretted, as the number of applicants for admission to the low-priced and charity wards is constantly much greater than can possibly be accommodated. The Baldwin pavilion is of precisely the same appearance and construction as the older building, and when it is opened the capacity of the hospital will be just doubled. Since the resignation of Marion Sims, early in the winter, no new chief-sur-

geon to the institution has been appointed, the number of patients being equally divided among Emmet, Peaslee, and Thomas. The first has his operations on Tuesdays, the second on Wednesdays, and the third on Saturdays; and only physicians with special invitations are admitted to these.

On Wednesday last Dr. Peaslee had an ovariectomy which presented several points of interest. He was to have performed it the week previous, but the condition of the patient did not permit. There were evidences of suppuration of the cyst which indicated a very unfavorable effect upon her system. The tumor was of the right ovary, and consisted of one large cyst and one small one, the latter situated at its lower portion, near the pedicle. An enormous quantity of semi-purulent fluid (probably five or six quarts) was drawn off, which was exceedingly fetid, and some of which was very thick and grumous. Yet the patient had been tapped only about ten days before, and twenty-five pounds of fluid obtained then. The latter did not contain such a large proportion of pus. The adhesions were very extensive and firm, and great care had to be exercised in their detachment; especially as some of them reached even to the liver. The omentum, instead of being spread over the anterior surface of the tumor, as is usually the case, was found rolled up above it. The peritoneum covering the intestines was completely engorged with blood, thus showing how imminent was the danger of extensive inflammation. The pedicle was of moderate length. It was secured by silk ligatures and then dropped into the abdomen. A small cyst, of the size of a bean, having been discovered in the left ovary, it was evacuated, and several small vessels were now ligated, as some little hemorrhage had been occasioned by the breaking up of the adhesions. A tube was inserted into the lower end of the abdominal incision, which reached behind the uterus into the cavity of the pelvis, for the purpose of washing it out, if necessary, with antiseptic fluids. This was first packed with dry cotton cloth, and then the latter moistened with a saturated solution of salicylic acid, so as to render it air-tight. Dr. Peaslee thinks an open tube is simply an invitation to septicæmia, and if it be true that this is occasioned by the entrance of bacteria into the abdominal cavity, it is effectually prevented by thus plugging up the tube. The edges of the wound were secured by eighteen or nineteen silver-wire sutures, about half an inch apart, as Peaslee prefers to have a large number in case excessive tympanitis should ensue. Over the whole a compress saturated with the salicylic acid solution was placed, and then the abdomen was covered with strips of adhesive plaster five or six inches in width, passed completely round the body. The operation lasted over an hour, being rendered somewhat tedious by the care necessary in detaching the numerous adhesions and by the time consumed in controlling the resulting hemorrhage. The prognosis was not very favorable, and the patient died about thirty hours afterwards. Dr. Peaslee also expected to operate on a case in private practice the

same week. From the physical signs elicited he supposed the tumor to be a monocyte, and accordingly tapped it, when he found it was in reality a polycyst. He is of the opinion that polycysts should never be tapped, unless one is prepared to go on with the operation of ovariectomy within twenty-four or forty-eight hours afterwards, as fatal effects may sometimes follow if this is not done.

The excitement in regard to affairs at the Presbyterian Hospital is still unabated, and we understand that several gentlemen have been approached by the authorities with the idea of finding out whether they would accept positions on the visiting-staff in the event of other possible "resignations" taking place. The action of the board of managers before spoken of has resulted in calling forth a protest, which has just been made public, signed by Drs. Markoe, Hamilton, Sands, Metcalf, Thomas, Van Buren, Wood, Flint, Emmet, Barker, Jacobi, Thomson, Draper, Loomis, Peaslee, and other leading medical men, without respect to college or clique. After expressing the regret with which they have learned of the summary dismissal of four of the visiting-physicians, who, so far as is known, were fully competent for the positions which they held, and discharged their duties with diligence and skill, they go on to say,—

"We believe that you have failed to realize the full character of your action. In thus discharging these gentlemen, you in effect proclaim your opinion that they are unfit for the positions which they held. By so doing you incur the responsibility of seriously injuring their reputation; and you have taken this grave step without preferring any charges, or assigning any reason for so doing. We believe you will admit that while you have acquired certain rights in assuming the position of manager of a hospital, you have also incurred certain obligations. While it is your right to appoint and dismiss the medical staff, it is also your duty to exercise this right for the best interests of the hospital. It is evidently your duty to obtain for the patients under your charge the best medical and surgical skill which our profession affords. We can hardly believe that any physician or surgeon of reputation will serve in any institution from which he is liable to be discharged without just grounds. We believe, therefore, that both as members of the medical profession and as citizens we are justified in asking that you shall make public the reasons for your late action."

During the past week the report of the Commissioners of Charities and Correction for the first three months of the year was presented to the mayor. From this we learn that the expenditures of the quarter, which, of course, came out of the pockets of the tax-payers of New York, amounted to \$368,818. This sum was divided among the items, salaries, supplies, out-door poor, and repairs to buildings and apparatus. About six hundred tons of coal were consumed in the institutions, and about four hundred distributed to the out-door poor. The number of inmates remaining in some of the institutions March 31 was as follows: Bellevue

Hospital, 732; Charity Hospital, 807; Fever Hospital, 4; Epileptic and Paralytic Hospital, 116; Hospital for Incurables, 117; Convalescent Hospital, 239; Nursery, Randall's Island, children, 481, adults, 110; Nursery Hospital, Randall's Island, children, 184, adults, 49; Infants' Hospital, Randall's Island, children, 277, adults, 192; Lunatic Asylum, Blackwell's Island, 1183; Lunatic Asylum, Ward's Island, 676; Idiot Asylum, Randall's Island, children, 170, adults, 150. The number remaining in the Penitentiary, Almshouse, Workhouse, City Prison, and other departments, brought the total population of the institutions up to 9718; of whom 6509 are males, and 3209 females. Number of applications for relief by the sick during the quarter, 3210; of these, 136 were rejected, 1309 were sent to Bellevue, 1451 to Charity, and 292 to various other hospitals. The Commissioners state that the Charity Hospital and other retreats on Blackwell's Island have received their careful attention, and that the supplies, therefore, have been plentiful and of good quality. Charity Hospital had 747 inmates January 1, and received 2324 during the quarter; 202 died, and 2062 were discharged. Its capacity is 2000 beds. The Smallpox Hospital is now under the direction of the Board of Health. Only 13 persons were in the Inebriate Asylum on Ward's Island, and the Commissioners think it a failure. During the quarter the Out-door Relief Department furnished money or coal, or both, to 16,806 families, comprising 61,079 persons.

The ancient and honorable the Society of the Cincinnati held their Triennial Convention a short time since in New York; when delegates from all of the seven States in which its members reside were present, and Hon. Hamilton Fish was for the seventh time elected President. The Committee of Arrangements consisted of Gen. John Cochran, Alexander Hamilton, Jr., and John W. Greaton; Gen. Cochran, its chairman, being a lineal descendant of Dr. John Cochran, Surgeon-General and Director-General of the hospitals of the Army of the Revolution.

The Central Dispensary, one of the newer and less richly-endowed institutions of the kind in the city, has made a very lucky hit in securing for a benefit at the Academy of Music the services of George Rignold, the most recent theatrical lion in New York. As this occasion will be his farewell to America, the receipts will, no doubt, be exceptionally large, for more than one fair creature in the best society has had her head turned by this Adonis of an actor. The tone of his letter accepting the proposition is admirable, and seems to show that he really desires the benefit to be as successful pecuniarily as possible. In it he says, "My present engagement terminates on the 5th of June, and I wish to sail for England as soon as possible after that date, but a few days may well be devoted to such a purpose in a city where I have met with so much kindness and generous hospitality. I am ready to place myself at your disposal. If you will allow me to suggest, you will announce it as my last appearance in New York, and I will play for you my original charac-

ter of *Amos Clark*, in the 'Bar Sinister,' in the study of which I had the assistance of its accomplished author, the late lamented Watts Phillips. This piece has never been acted in New York, so far as I can learn, and it met with great success abroad, and was the means of making me more popular than any other character I have sustained. I trust it will prove a substantial benefit to the charity."

The following changes and appointments at the colleges are announced: Medical Department University of New York,—Dr. Alfred C. Post resigned from the chair of Surgery, and elected Emeritus Professor of Clinical Surgery. Dr. John T. Darby, formerly of South Carolina, and late Professor of Surgical Anatomy in the University, appointed to Dr. Post's place. College of Physicians and Surgeons,—Dr. Alonzo Clark elected President of the College, in place of the late Dr. Edward Delafield. Dr. Thomas F. Cock, Trustee, to fill the vacancy left by the death of Dr. Delafield. Dr. Francis Delafield, Adjunct Professor of Pathology and Practical Medicine. Dr. John G. Curtis, Adjunct Professor of Physiology and Microscopic Anatomy.

PERTINAX.

PROCEEDINGS OF SOCIETIES.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

WEDNESDAY, APRIL 7, 1875.

DR. WILLIAM S. FORBES read the history of a case of *acute tetanus*, beginning on the fourth day after an extensive burn, and advancing with great rapidity,—having, in forty hours from its commencement, a temperature of 102°, a pulse of 133, and a respiration of 32 per minute,—presenting marked opisthotonos, with trismus and a horrid tetanic grin; and having the muscles of deglutition considerably involved, together with paroxysms of brief and painful spasms which yet were perfectly controlled by inhalations of nitrite of amyl, which was given in doses of five drops twice a day for forty-six days.

S. H., aged 17, a brickmaker, was admitted to the male surgical ward of the Episcopal Hospital on the afternoon of the 5th of February, with burns of his body and extremities from hot iron, which had been accidentally blown against him from a foundry. He had walked to the hospital, a distance of a mile and a half, the air at the time being very cold. He was burned severely from his waist to his heels; the greater portion of the burn being of the second and third orders of Dupuytren. He was at once put to bed, his wounds dressed with linseed oil and lime-water, his whole person enveloped with cotton, and half a grain of sulphate of morphia administered and repeated five hours later. The following evening he had a chill, and complained of pain in his extremities and along the spine. Morphia was given, the oil-dressing was removed, and replaced by the ceratum resinæ acidum. The following two days he felt quite comfortable; took food and a little morphia, which was the last that he received.

On the 9th he had no desire for food; complained of soreness, and had a severe convulsion in the evening.

On the morning of the 10th, he had stiffness of the jaws, with pain in the back of his neck, and his mouth began to assume a tetanic grin. He was given milk

and beef-tea, and five ounces of brandy during the twenty-four hours.

On the morning of the 11th there was marked opisthotonos with trismus, accompanied with great difficulty of swallowing, which began the evening before. His skin was hot, temperature 102° F.; his pulse 133, and his breathing 32 per minute. A teacupful of beef-tea was ordered every two hours, alternately with milk; to be taken day and night, and eight ounces of brandy in the twenty-four hours. He had a convulsion during the night.

In view of the excellent effects obtained by the use of nitrite of amyl in epilepsy, angina pectoris, etc., it was determined to try the virtues of the same drug on the contraction of the muscles in this case of tetanus, and to try it alone, and without the intervention or administration of any other medicinal agent whatsoever, that its efficacy might be properly tested, and that it should stand or fall as the issue of the event, in this case at least, might determine. Nitrite of amyl had been used previously in three cases of acute tetanus, but in only three cases, and each case terminated successfully, but other and well-known agents were at the same time administered. This case is the first in which amyl has been used alone, and successfully, and its action recorded. The amyl was first administered on the evening of the sixth day after the accident, and about forty hours after tetanus first discovered itself. Before the three drops had half evaporated, the heart's action became more quiet; and at each inhalation of the amyl afterwards it was generally observed to have a quieting effect on the heart's action. Towards the latter part of the treatment the pulse was among the eighties, although on giving the patient five drops on the 4th of April, six days after he had ceased to inhale five drops twice daily, the heart's action was 132 and tumultuous. The eyes were suffused, the skin of the face and neck became very much congested; indeed, the whole surface of the body was more or less congested; but this soon passed away when the amyl was withdrawn. The three drops had scarcely begun to cause congestion when there was evinced a tendency to gape, and a few days afterwards gaping and yawning both took place at each inhalation until the administration of the drug was discontinued.

This gaping and yawning was produced in each subsequent administration of the drug, which was given twice daily. A marked improvement was at once manifested in all his symptoms.

On the 14th, having another spasm, the dose was increased to five drops twice daily.

The amyl in the hospital giving out on the morning of the 18th, it was not replaced until the evening of the 20th. During this time he grew rapidly worse; the opisthotonos and the risus sardonius both returned, and his pulse and temperature rose rapidly. On recommencing the inhalation of amyl he felt better almost immediately, and from that time progressed steadily to complete recovery.

On the 29th of March, forty-six days after the first dose of the amyl was given, the patient appeared to be perfectly well. He could walk about, and eat and drink, and enjoy himself in every way as before the attack, except having a feeling of weakness. The amyl was now discontinued; he had inhaled one ounce.

In reviewing the results of the observations of pathologists in cases of tetanus, Dr. Forbes stated, we find that they all point to disintegration of tissue as an established fact. We also find through the researches of physiological chemistry that the capability which muscle has of exercising its functions depends for its strength upon the presence or absence of certain matters formed in this muscle itself by the *decomposition* of the muscular tissue. Lactic acid and kreatine are the products

of decomposition of muscular substance; they are to the muscle exhausting matters; they act in an opposite manner on the peripheral nervous system; they elevate the excitability of the muscular nerves; *they are muscular stimulants*. And we find that muscular contraction depends on the forces of the muscular substances set free and rendered available by increased metamorphosis of matter, and that the chemical bodies mentioned, lactic acid and kreatine, produce no definitive alteration of the muscle by their presence, but that their effects may be destroyed by their removal. The simple removal of the exhausting stimulating matters, *lactic acid* and *kreatine*, from the muscle, restores the normal vital properties of the muscle.

What, then, are we to learn from these observations and this case of tetanus? We learn that tetanus is the result of an augmented disintegration of muscular tissue; that the products of this disintegration, lactic acid and kreatine, further excite the nervous peripheries until by reflex action there is established a "violent and painful contraction of the voluntary muscles," which is long continued and "heretofore uncontrollable;" that in traumatic tetanus the augmented disintegration of muscular tissue is caused by an increased excitation of the nerve-peripheries exposed; that in idiopathic tetanus there is a self-generated power akin to the poison of rabies and to strychnia, exciting the nerve-peripheries, which, by reflex action, causes the augmented disintegration of muscular tissue, and the products of disintegration, lactic acid and kreatine, which further excite the nerve-peripheries until there is established the condition known as tetanus.

Impressed with this as the pathology of tetanus, the appropriate treatment should be the use of those agents which are known to prevent the disintegration of tissue, which will lessen the irritated nerve-peripheries, which will sustain nutrition and advance the elimination of the morbid products.

The *modus operandi* of the nitrite appears to be by arresting the process of oxidation in the tissues, and the same reasons which lead to its use in tetanus—namely, to prevent the disintegration of tissue, and to lessen the irritated nerve-peripheries while nature is eliminating the morbid products—should also cause it to be employed in hydrophobia.*

SELECTIONS.

TRANSFUSION.—The question as to the practicability of using the blood of an animal belonging to a different species has lately been to some extent determined by Landois (*Centralblatt*, 1874, No. 27) and Ponfick (*Virchow's Archiv*, vol. 62), who have shown that the moment the amount of such blood exceeds a small and fixed quantity, unfavorable symptoms will under all circumstances develop themselves. Ponfick discovered the presence of free hæmoglobin in the blood-plasma in these cases, and, as a natural consequence, in the various organs and their secretions. He draws attention to the anomalous presence of this substance, which is never found in normal blood, in the blood-plasma, and, considering that the function of the kidneys is to get rid of such a substance, he concludes that the deleterious effects of such transfusions are caused by the inability of these organs to perform the extra work thus imposed upon them. That the kidneys are hereby seriously inflamed is proved by finding after death a copious exudation of plasma into the lumina of the

* Since this paper went to press, the last number of *New Remedies* has been received, containing a note of a case of tetanus successfully treated by inhalations of nitrite of amyl, reported by Funkel, of Berlin.

uriniferous tubules, which at once causes an insufficient amount of urine to be secreted. Death takes place just as it does in cases of uræmia, from suppression of urine, the symptoms being in both cases similar. The success which Dr. Hasse, who always transfuses lamb's blood, professes to have obtained is not above question, and the results obtained by other operators, as, for instance, Birsch-Hirschfeld and Ries, have not come up to the expectations which a perusal of Dr. Hasse's publications is calculated to awaken. In three cases in which I have lately been called upon to perform the operation, I used defibrinated human blood. The ordinary operation was performed twice for excessive anæmia (pseudo-leukæmia), and once in a case of poisoning with carbonic oxide. In one of the cases of anæmia and in the case of poisoning with carbonic oxide, the operation was quickly followed by the patient's recovery. The other case of anæmia, which occurred in a young man aged 27, proved fatal five hours after the operation, with all the symptoms which usually accompany death after the transfusion of animal blood. None of the patients complained during the operation either of violent stitch or pain in the back, which is a constant symptom when animal blood is used. In all three the temperature rose during the two hours following the operation to 104° and 104.9° F., and then sank quickly to normal. There were no further symptoms. The blood transfused was on each occasion obtained from patients who were suffering from some slight bronchial affection. Immediately after the operation, the patient, who, as above mentioned, afterwards died, felt quite well, and, like the other two, his pulse was stronger and fuller than it had been previously, and his breathing, which had been somewhat hurried before the operation, became quieter. During the third hour after the operation he began to complain of want of breath, and became very restless, tossing himself about in bed, and died quite suddenly without presenting any very special symptoms.

The urine that was found in the bladder was the color of blood, and contained some cylinder-shaped bodies, which were composed of a finely granular, yellowish-red mass, which contained, however, no red blood-corpuscles, but on which the usual hæmoglobin markings were plainly visible.

At the post-mortem, the heart was found slightly hypertrophied and fatty. The spleen was slightly enlarged; there was extravasation of blood beneath the serous membranes, especially the pericardium and pleura. Neither macroscopically nor microscopically could any alteration be detected in the vessels. The kidneys were large and unusually pale. Under the microscope the epithelium of the straight tubes appeared dull. Here and there at the junction of the straight and convoluted tubes broad cylindrical bodies were found which corresponded exactly with those in the urine. All this agrees accurately with the post-mortem appearances described by Ponfick and Landois as occurring in cases that proved fatal after the transfusion of animal blood. I have not quite made up my mind as to what were the conditions in this case that led to the fatal termination. It seems, indeed, probable that there was, if I may be allowed to use the expression, a sort of morbid predisposition of the whole circulating system and its contents. From the state of fatty degeneration in which the heart was found, it is plain that there must have been some interference with the nutrition of the vessels, and a considerable change in the constitution of the blood. Now, why should not blood whose chemical and morphological elements have undergone such a change bear the same contrast with healthy blood, as it has been found by experiment that lamb's blood does with dog's blood?

It will be very hard to determine in successful cases

what influence the transfusion has had, or if, indeed, it has had any. But the operation itself is so simple, and its good effect so notorious, that it certainly deserves to be performed oftener than it is. In the case of leukæmia that I transfused successfully, the operation had a marked influence on the constitution of the blood. For a drop of blood obtained before the operation by pricking the finger appeared of a light blood-red color and watery; while a drop obtained in a similar manner after the operation had a florid red color, and seemed thicker. Both before and after the operation the red blood-corpuscles presented a peculiar pale and glistening appearance, and their number was not perceptibly increased by the operation. I may further remark that the eight cases in the Augusta Hospital, in which Dr. Kuster lately performed transfusion with lamb's blood, all turned out unsuccessful. These eight cases all died, and in none of them was the good effect of the operation perceptible for more than from ten to fourteen days. In one case the operation was probably the immediate cause of an attack of hæmoptysis, and in another it was followed by protracted fever. All the patients complained during the operation of violent pain in the back, and great difficulty in breathing. From half an hour to an hour after the operation they were seized with a rigor, followed by a rise in temperature, which was again dissipated in from five to six hours. It is only fair to mention that all these patients were suffering at the time of the operation from some severe surgical injury.—*Dr. C. A. Ewald, Charité, Berlin; from Irish Hospital Gazette.*

GLEANINGS FROM OUR EXCHANGES.

LUXATION OF TESTICLE.—Dr. Hess reports a case of luxation of the right testicle. An artilleryman, thirty-one years of age, was knocked over by the rebound of a cannon, and was found lying upon his face unconscious, his sabre between his legs. On his return to consciousness a small tumor was discovered in the upper part of the thigh, and was supposed to be caused by an effusion of blood. Two days later, on a more careful examination, the right testicle was discovered underneath the skin on the inside of the thigh, at a level with the lower border of the scrotum. It could be moved upwards, but was very painful. The right side of the scrotum was empty. At the end of a few days the reduction of the displaced organ was effected. The author thinks that the testicle was displaced by being pushed back to the inguinal canal, and in consequence of the resistance offered by the sabre could not return to its place, but was pushed under the skin of the thigh.

TESTING FOR CHLOROFORM.—E. Rennard describes, in *Pharm. Zeitschrift für Russland*, an interesting case of detecting chloroform in a body which had been dead seven days. About sixty grammes of the liver and intestines, with one hundred and twenty grammes of blood from the same, were distilled, and ten cubic centimetres of a perfectly clear distillate obtained. From three to five cubic centimetres of this liquid were mixed with two cubic centimetres of an alcoholic solution of potash and one drop of aniline, or some salt of aniline, and the test-tube gently warmed by dipping it in hot water. The disgusting and penetrating odor of isonitric acid was at once observed. This test, which was devised by Prof. A. W. Hoffman, will detect the presence of one six-thousandth part of chloroform, and may be employed where all the usual tests fail.

To bleach sponge, wash first in weak muriatic acid, then in cold water; soak in weak sulphuric acid, wash in water again, and finally rinse in rose-water.

MISCELLANY.

THE MEDICAL NIGHT-SERVICE OF ST. PETERSBURG.—The *Voix* gives some details of the practical working of this new institution, already referred to in these columns, and which has now been in operation for a twelvemonth. At first, this new night-service, founded by the private exertions of a few medical men, had many difficulties with which to contend; but perseverance triumphed in the end, as it usually does. This novel institution is now found to be extremely useful to the inhabitants of St. Petersburg, and reckons persons of all ranks and means among its clients. The medical men on duty are always ready to render the services asked at their hands, without any previous knowledge that their labor will prove remunerative; neither do they shrink from going, when required, to the most dangerous and notorious localities. The number of visits made and carefully registered during the current year amounts to 1024, of which the greatest number was in January, when they amounted to 152; the maximum of visits made in one night being six, and the minimum three. The patients comprised 524 men, 363 women, and 137 children of both sexes. These nocturnal duties were performed by fifteen of the permanent staff and thirty-five occasional helpers. The fees paid by persons in good circumstances have been utilized in completing the necessary arrangements for this night medical service and in organizing small surgeries, where the necessary appliances may be always found at hand. The example thus set by the medical profession at St. Petersburg has been followed by the sincerest of flattery, "imitation," at Moscow, Odessa, Warsaw, and other large cities of the north.—*London Medical Record*.

CRIME AND AUTOMATISM.—Dr. Despine, in his *Psychologie Naturelle*, gives a striking analysis of the mental status of the criminal classes. Attracted by the singular want of emotion displayed by most criminals, Dr. Despine was led to a thorough examination of court records and other sources of information. He arrives at a belief in the entire absence of moral sense in this class. He says that free-will, which in the normal man is only controlled by the sense of duty, in the criminal has no such counter-balance, this sense being wanting. His acts are, therefore, mentally automatic, the result of the strongest instinct, appetite, or passion prevailing at the time. Most criminals are, therefore, morally irresponsible, no matter how great the crime as against society. Like brutes, savages, and idiots, they yield to natural appetites and passions, unrestrained and unreproached by any feeling of impropriety, although intellectually cognizant of the moral standards of society. Hence their remarkable *sang-froid*, and the superficial character of any apparent reformation or conversion. Dr. Thomson, resident surgeon to the General Prison for Scotland, at Perth, finds his experience confirmatory of the views of Despine, and, in a paper published in the *Journal of Mental Science* for October, 1870, recognizes various degrees of "moral insensibility."

A MATCH UNDER THE MICROSCOPE.—Those who are fond of investigations with the microscope will find a beautiful object in the head of an ordinary parlor-match. Strike the match, and blow it out as soon as the head has fused sufficiently to cause protuberances to form on it; on that part of the head which took fire first will be found a white, spongy formation, which, under the microscope and with a bright sunlight on it, has the appearance of diamonds, crystals, snow, frost, ice, silver, and jet, no two matches giving the same combination or arrangement.—*Scientific American*.

THE Prince of Bavaria, whose sister married the Crown-Prince Rudolph of Austria, has, it is stated, adopted medicine as his profession. By all accounts he will be a very successful practitioner, for he has not only received a diploma, but he has within the last few days performed a most difficult operation at the Munich Ophthalmic Hospital.—*Boston Medical and Surgical Journal*.

WE desire to call attention to the Medical Charts of the Case Record Company, as a means of facilitating accurate note-keeping; the prices are, five cents each, fifty cents per dozen, three dollars per hundred.

ON the 3d of March the first stone of the Anatomical School of the new Faculty of Geneva was laid with great pomp.

THE Cross of Commander of the Norwegian Order of St. Olaf has been conferred on Professor Sigmund, of Vienna.

DR. G. L. CARIUS, professor of chemistry at Marburg, died on April 26, in the forty-sixth year of his age.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U. S. ARMY, FROM JUNE 1, 1875, TO JUNE 7, 1875, INCLUSIVE.

RANDOLPH, JOHN F., SURGEON.—Relieved from duty at Camp Robinson, and assigned to duty at Fort D. A. Russell, Wyoming Territory. S. O. 64, Department of the Platte, May 29, 1875.

FRANTZ, J. H., SURGEON.—Assigned to duty as Post-Surgeon at Fort Preble, Maine. S. O. 105, Military Division of the Atlantic, May 26, 1875.

WEEDS, J. F., SURGEON.—Assigned to duty at Nashville, Tennessee, as Post-Surgeon. S. O. 71, Department of the South, June 2, 1875.

LORING, L. Y., ASSISTANT-SURGEON.—Granted leave of absence for one month. S. O. 38, Department of Arizona, May 18, 1875.

HARVEY, PHIL. F., ASSISTANT-SURGEON.—When relieved by Surgeon Frantz, assigned to duty at Fort Independence, Massachusetts. S. O. 105, c. s., Military Division of the Atlantic.

HOFF, JOHN V. R., ASSISTANT-SURGEON.—Granted leave of absence for one month. S. O. 64, c. s., Department of the Platte.

ADAIR, G. W., ASSISTANT-SURGEON.—Relieved from duty at Ringgold Barracks, and to proceed to Fort Duncan, Texas, reporting upon arrival to Lieutenant-Colonel Shafter, for duty in the field. S. O. 106, Department of Texas, May 31, 1875.

SKINNER, J. O., ASSISTANT-SURGEON.—Relieved from duty in Department of the Columbia, and to report in person to the Commanding General, Department of the South, for assignment to duty. S. O. 111, A. G. O., June 4, 1875.

HAMILTON, JOHN B., ASSISTANT-SURGEON.—Assigned to duty at Fort Colville, Washington Territory. S. O. 64, Department of the Columbia, May 19, 1875.

SATURDAY, JUNE 19, 1875.

ORIGINAL COMMUNICATIONS.

TUBERCULAR ULCERATION OF THE LARYNX AND TRACHEA.

Read before the Pathological Society of Philadelphia, April 8, 1875.

BY R. M. BERTOLET, M.D.

CONSIDERABLE diversity of opinion has for a long time prevailed among pathologists, and even exists at the present day, as to what actually constitutes the morbid process which underlies and induces the extensive ulcerations of the laryngeal and tracheal mucous membranes so frequently marking the termination of pulmonary phthisis. Modern research has dissipated many so-called tuberculous masses. Thus, the "crude tubercle" of Laennec has been resolved into simple caseous pneumonia; while "phthisis renalis" has been proven to be, in the majority of cases, minute capillary embolism, or inflammatory foci; the miliary tubercle being something altogether accidental.* This same tendency to limit strictly the term "tuberculous" to cases in which the actual presence of the miliary granulum is clearly demonstrable has likewise been applied to the affections of the larynx, with the result that now many deny *in toto* the eruption of tubercles in this site of the body.

The unusual activity which has been awakened in the study of diseases of the throat since the invention of the laryngoscope places it beyond a shadow of doubt that much of what was formerly designated as laryngeal phthisis has no connection whatever with tuberculosis. Yet I think the mark has been over-reached by those who disclaim entirely the tuberculous character of all laryngeal ulcerations. The proneness which tubercle, when seated in the laryngeal mucous membrane, exhibits towards necrobiosis explains, in a measure, the fact why, in this site, it so often escapes detection; tubercle being no longer recognizable as such when once it has undergone caseation and softening. There is nothing characteristic in the broken-down debris of tubercle.

In the literature on this subject we find two views entertained,—one group of authors maintaining that tubercle does not occur in laryngeal ulcerations, while the others ascribe an important rôle to tubercle in these affections. Among the former may be cited Rühle,† who, after years of diligent search, found but two specimens of miliary tubercle among hundreds of laryngeal and tracheal ulceration of phthisical patients. Most frequently simple catarrhal or follicular ulcerations were observed; the latter especially at those points of the larynx where the racemose glands are aggregated,—namely, upon the posterior surface of the epiglottis, upon the upper portion of the posterior laryngeal wall,

and in the Morgagnian ventricles. Türk,‡ also, and with him many others, adopt the view of their mode of origin which was first studied and promulgated by Rheiner.§ The catarrhal inflammation which forms the basis for the ultimate loss of substance is characterized as a destruction of the epithelium, and a thick cellular infiltration of the mucous and submucous tissues. This infiltration Rheiner regards "as a uniform proliferation of pre-existing elements." The margins of the ulcerations are usually pale, and thickened by a serous or oedematous infiltration. Papillæ, which, according to Rheiner, do not normally occur in the larynx, appear in the vicinity and upon the margins of old ulcers.

Rindfleisch|| very graphically describes the various pathological appearances induced by the chronic infiltration of the laryngo-tracheal glands, and asks, "If the weightiest and gravest disturbances of the larynx and trachea are alone induced by catarrhal inflammation and ulceration, what is left for tuberculosis to perform? Do tubercles at all occur in 'phthisis laryngea,' and what rôle do they play?" This author, while admitting having found cellular foci in still intact portions of the connective tissue recalling the appearances of miliary tubercle, ascribes to them no higher value than that of a permanent irritant, and thus accounts for the persistency and tendency to recur which is so characteristic of these catarrhal inflammations.

Of those who, on the contrary, view the lesions in question as decidedly tuberculous, we need but mention Virchow and Rokitsky. According to the latter,¶ tubercles occur in the laryngeal mucous membrane, as in most other mucous membranes, in the form of small granulations or massive infiltrations. From their destruction ulcerations appear, which are, therefore, of positive tubercular nature. These often extend into the submucous tissue, have hard, raised, undermined edges, often having "papillary vegetations" covered with excessive epithelial formations. In the vicinity occur injection, redness, swelling, and oedema. This is the mode of the development of the primary tuberculous ulceration, which by confluence with others, and partly by the breaking up of fresh tubercles upon the margins, brings about the secondary ulcer.

Virchow** as positively asserts the presence of tubercles in the larynx, and further points out that when seated very superficially in the membrane they are apt to soften and form small, shallow, simple tubercular ulcerations without even having ever undergone caseation or attained a size appreciable to the naked eye.

After excluding the catarrhal ulcerations, which have been so often mistaken for tuberculous, there still occur a limited number of ulcerations in which it is possible to demonstrate the existence of miliary tubercles in those parts of the mucous membrane

where the mucous glands and their ducts remain unaffected. In one of the three specimens of the human larynx and trachea which are herewith presented to the Society, this is very notably the case; the extensive loss of substance is remarkably limited to the mucous membrane directly covering the tracheal rings and the vocal cords, and although a number of the tracheal cartilages are laid bare by the ulcerative process, yet we find the intercartilaginous spaces, the posterior surface of the epiglottis, Morgagnian ventricles, and other points which are most abundantly supplied with mucous glands, unaffected.

In the two other specimens, the ulcerations are more extensive, but limited principally to the glandular localities; yet at certain distances from the œdematous and papillary margins I have also found in them unmistakable miliary tubercles beneath an attenuated epithelial covering. All of these specimens were obtained from exquisitely pronounced cases of tuberculosis. I will not delay to give their clinical histories, save a brief synopsis of the first case, which is interesting not only from the fact that it is eminently a tubercular and not a follicular process, but illustrates the probable manner of infection (auto-inoculation), and the extreme rapidity with which these ulcerations may be developed.

J. W., aged 36, a laborer, native of Bavaria, was admitted into the German Hospital March 19, 1875, and died upon the 25th of the same month. He had been an inmate of the institution upon two former occasions during the last year and a half, then presenting all the physical and subjective symptoms of chronic pneumonic processes in the apices. The troublesome cough and abundant expectoration were successfully combated upon both occasions, and the patient, rapidly regaining his strength, was enabled to resume his ordinary labors, which subjected him to much out-door exposure. No laryngeal complications presented themselves in his earlier attacks, but upon his last admission there was marked aphonia; hoarseness only developed a few days before. The sputa were muco-purulent, but not very abundant.

There were at once detected all the physical signs of small vomicæ in the apices, and increased vocal fremitus, and impairment of the resonance, extending posteriorly to the base of the lungs. Subcrepitant râles, both anteriorly and posteriorly, were heard upon auscultation; cavernous respiration in the infra-clavicular region. The heart-sounds were normal. The urine was of a high specific gravity, loaded with urates, but free from albumen.

The patient had been actively employed until within a week previous to his entrance into the house, and presented a robust appearance, which was far from indicating the serious malady with which he was affected. However, the previous history, together with the rapid pulse, the hurried respirations, and the extremely high temperature (never under 100° F. during the entire six days) left little doubt that acute tuberculosis had supervened upon the breaking down of old caseous foci seated in the lungs.

The patient very rapidly lost strength and emaciated; the bodily temperature continued excessive in spite of large doses of quinine and other antipyretic remedies. There were, as is ordinarily observed in these cases of tuberculosis, marked morning exacerbations, the temperature exceeding by three or four degrees that noticed in the evening. The febrile disturbances were attended by digestive derangements, and, upon the last few days,

profuse diarrhœa set in; stools slightly tinged with blood.

A laryngoscopic examination showed a congested condition of the entire laryngeal mucous membrane, with a few punctiform yellowish prominences upon the posterior surface and margins of the epiglottis. Only the most superficial ulcerations could be detected upon the upper and inner surfaces of the vocal cords. No satisfactory view of the trachea was obtained, and, not desiring to fatigue the patient, all further attempts at examination were discontinued.

Autopsy.—The body was noted as considerably emaciated; firm pleuritic adhesions existed over the upper lobes; about an ounce of serous effusion in both pleural cavities. A caseous infiltration partially solidified both the upper lobes; disseminated throughout these, and less uniformly in the lower lobes, were numerous gray miliary tubercles. A cavity the size of an English walnut, with ragged walls, had formed in each apex. There was peribronchial induration of the adjacent bronchioles, which at many points were dilated and plugged with yellow, cheesy masses, while the mucous membrane was inflamed and at many places ulcerated. There was hypostatic œdema in the posterior and pendent portions of the lower lobes; bronchial glands enlarged. There were numerous equatorial ulcerations of the small intestines, the mesenteric glands being moderately enlarged. There was considerable intumescence of the liver, spleen, and kidneys, the former being fatty, and the latter showing cloudy swelling of the cortical epithelium. No miliary tubercles were detected in these organs.

The larynx and trachea obtained from this case, as previously stated, exhibit very extensive destruction of the mucous membrane covering many of the tracheal rings, and superficial erosions upon the vocal cords. Portions of this and of the other specimens were frozen, and thin sections made of them in the fresh condition, while other parts were hardened in a solution of chromic acid. The result of the microscopic examinations may be briefly summarized as follows: a diffuse cellular infiltration of the tissues around the mucous glands and their ducts, extending from the margin of the ulcerations far into the adjacent mucous membrane, giving it a finely granular appearance. Under higher powers this resolves itself into a lymphadenoid tissue with cells of a roundish shape, usually having a large nucleus. A finely reticulated net-work, generally fibrillated, or else minutely granular, separates the cells. Often the glands are hypertrophied and their ducts occluded with secretion; yet this peculiar net-like tissue is also found around follicles which present a normal appearance. It is also found at points, but always sub-epithelial, where no ulcerations have yet occurred, the mucous membrane being still intact. Very often, however, the epithelial covering is elevated and attenuated, beneath being found a circumscribed mass with a large, compact, granular centre. The readiness with which the periphery of this nodule takes up carmine, its multinuclear giant cells, its reticulum, and its entire appearance, leave room for no other interpretation than that of tubercle. Confirmatory observations of these appearances, with most excellent microscopic illustrations, have been made by Wahlberg,* who, in his exhaustive studies upon this subject, also minutely

* Medicinische Jahrbücher, 1872, Taf. VII.

describes the various alterations occurring in the squamous and cylindrical epithelium. Wahlberg ascribes the localization of this peculiar adenoid infiltration in the parts around the mucous glands and their ducts to the fact that they are surrounded by an extremely well-developed capillary net-work.

I have been very much interested in noting the liability, in this and in a great many other specimens where the tubercular and not the catarrhal processes predominated, of the mucous membrane covering the sharp projecting edges of the tracheal rings and vocal cords to become involved first. If we consider how nearly uniformly successful the attempts at inoculation with tuberculous material have proven, the sputa alone of tuberculous patients sufficing, to say the least, it cannot but appear plausible that the same matter should possess equally infectious properties whilst still remaining in the human body, especially so when the circumstances attending its engrafting are so unexceptionably favorable. The tenacious sputa clinging to the tracheal walls and exerting their greatest pressure and friction upon the projecting ridges not only exercise a deleterious influence upon the epithelium, but also cause a hyperæmic condition of the underlying capillaries; the moment arrives when the sputa are loaded with tuberculous elements, some of them still, perhaps, possessed of amœboid movements, and the ground for this tubercular seed is in excellent tillage, and freely supplied with running streams of lymph and blood.

Another reason suggesting and favoring this view of a local infection by the direct contact is the infallible precedence of a tubercular process in the lungs. This statement is only apparently at variance with the ground held by many of the best laryngoscopists, that tuberculous laryngitis may be developed before there are any lung-complications, since they are disposed to designate by this same term ulcerative laryngitis even when dependent upon mere chronic follicular inflammations; and I doubt very much whether a rigid discrimination beyond the mere site of the ulcerations is possible, for miliary tubercles are not recognizable as such by the laryngeal mirror.

In all the autopsies where I have succeeded in detecting true tubercular ulcerations of the throat and windpipe, I have invariably found tubercles existing in the lungs. Should this view of their growth in the trachea and larynx by local inoculation be corroborated by further observations, then the statement made by Louis, that the sharp secretions of the sputa excoriate the mucous membrane, is after all not quite so absurd. Curiously enough, however, Louis denied the tuberculous character of all laryngeal ulcerations.

A CASE OF HÆMOPTYSIS PRECEDING AND ACCOMPANYING LABOR.

BY HENRY B. REED, M.D.

MRS. M. K., æt. 38; born in Ireland; washer-woman by occupation; of intemperate habits; came under my care May 5, 1875. I found her sitting

in a chair, with her feet in mustard-water, and having a basin in her lap containing about a teacupful of uncoagulated, bright red, and frothy blood. She wore a very anxious expression, and she told her husband, who was near her, that she was dying. Her pulse was 120, and full; there was great uneasiness in the chest, and great difficulty in breathing. Skin was covered with a cold sweat.

The history of the case, as derived from herself, is as follows. Early in the fall of 1874 she took a severe cold, while washing, which laid her up for about a week, and since that time she has had a cough and shortness of breath on slight exertion, loss of flesh, and, lately, swelling of the feet, cough more persistent, especially at night, and almost always accompanied with the expectoration of frothy, greenish, and yellow sputa, sometimes tinged with blood, and profuse and exhausting night-sweats. She was pregnant, and had expected to have been delivered on the day previous to the one on which I first saw her. The hemorrhage from the lungs came on while "hanging up clothes." Both her father and mother died with lung-troubles. I did not deem it necessary or advisable to make a prolonged physical examination when I first saw her, but simply placed my ear to the chest, and detected low gurgling sounds at the apex air-tubes of the right lung. Ice was applied to the chest, and ten grains of gallic acid given every half-hour for two hours, to insure an arrest of the hemorrhage. Spt. ether. comp. was given in one-drachm doses every three hours, to relieve the dyspnœa.

May 6.—Patient quite comfortable. No signs of approaching confinement. During an occasional cough, the patient would spit up dark clots with sputa.

May 8.—Up to this time the patient has remained in a comfortable condition, but is only able to rest while sitting up. 9.30 P.M. I found her in labor-pains, with a second hemorrhage from the lungs. I determined to accomplish as hasty a delivery as possible, on account of her great efforts in breathing. The bag of waters was ruptured, the forceps applied, and she was delivered of a fine, large, female child. 3i of vin. ergotæ administered. The hemorrhage ceased in a few minutes, the placenta came away, and the oppression in breathing was greatly relieved.

May 9.—Physical examination revealed an extensive cavity at the apex of each lung. Feet of the patient much swollen, and pit on pressure. Some dyspnœa.

Since May 9, the patient has been sinking gradually, notwithstanding the administration of tonics and nourishing diet. She has had no more trouble from hemorrhage, and has been feeling easy.

Wednesday, May 26.—Patient died.

NOTES OF HOSPITAL PRACTICE.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

SERVICE OF PROF. NEILL, MAY 15.

Reported by DR. J. WILLIAM WHITE.

GONORRHOEA.

CASE I.—We have here to-day in this lad a typical case of gonorrhœa, and, although you have already seen many similar cases, I will take this opportunity of impressing upon your minds a few of the more important points connected with this disease and its treatment. In the first place, remember that we are speaking of a true specific affection, not of an ordinary urethral catarrh, — of a disease which in all cases results from the applica-

tion of a peculiar poison, which follows impure and indiscriminate connection, and which is highly contagious. It is a true venereal disease, that term at the present day being used to include the local contagious chancre or chancroid, syphilis, and gonorrhœa, each of which diseases propagates itself and no other. We must not, therefore, consider that it is to be compared with the various non-specific inflammatory diseases that may attack the genito-urinary organs, or with the mucous or muco-purulent discharges which take place from the eyes, the nose, or the bronchi. These are usually not inoculable and not contagious. Neither will these or similar diseases produce gonorrhœa. It is not a case of evolution from bronchitis or cystitis, but arises from the presence of a specific germ, which has a definite life and individuality, and did not grow out of anything else.

With the usual symptoms and causes of this disease I presume you are all familiar. After the exposure to contagion there is a stage of incubation, lasting from three to five days, followed by a sense of heat and itching around the external meatus, the lips of which become red and swollen. On squeezing the urethra, a few drops of mucous pus can generally be forced out. The discharge becomes more abundant; there is intense pain during urination, which is often more frequent than natural; chordee occurs; there is often some constitutional disturbance, fever, headache, etc., and then these symptoms subside, the inflammation becomes subacute, and, under proper treatment, disappears in the course of a few weeks.

In regard to the treatment of this disease, a very false notion prevailed among our professional predecessors, and has been inherited from them.

The common treatment of gonorrhœa used to be, and to a certain extent still is, the administration of stimulating resinous diuretics, principally cubebs and copaiba. The abuse of these medicines is worse than the disease itself, and they have undoubtedly been the cause of much of the chronic urethritis and cystitis which now exist. They have also been productive of much dyspeptic trouble, especially since the introduction of capsules, admitting of such large doses. You may therefore lay this down as a rule in the treatment of gonorrhœa: never begin with cubebs or copaiba. In such a case as this, and indeed in nearly all cases, at this early and inflammatory stage I should direct the following prescription:

R Potassii bitart., ℥iv;
Potassii nitrat. (pulv.), ℥iii;
Potass. et antimon. tart., gr. i.

This should be ground in a mortar and thoroughly incorporated, and then divided into twelve powders, one of which is to be taken three times daily.

The result will be at once an increased action of the kidneys and the whole genito-urinary tract, which will diminish the vascularity and hyperæmia of the urethral mucous membrane. The discharge will, perhaps, at first be somewhat increased, and it is as well to mention the possibility of this to the patient, but it will then in its turn diminish, and in ten days will almost invariably be much less. In conjunction with this treatment you may order urethral injections, consisting at first merely of cold water, and afterwards of some astrigent, such as the sulphate or chloride of zinc or nitrate of silver, but never stronger than half a grain or a grain to the ounce. At the same time, the amount of solid food should be restricted, large quantities of water and alkaline drinks should be taken, and the use of spirituous liquors, violent exercise, and sexual excitement should be strictly avoided. The prejudice which exists against coffee, salt meat, etc., I believe to have no philosophical basis.

BUBO FROM INVERTED TOE-NAIL.

Case II.—This patient is a plumber by trade, twenty years of age, and is, as you see, of a lymphatic temperament. He has been out of work for some time, and is rather poorly nourished. About six weeks ago he noticed a swelling in his groin, which was at first tender and painful, but which gradually became insensitve, although continuing to increase in size. There is no existing venereal disease, and he denies having been the subject of any,—which is probably true, as there are many cases of bubo not connected with any specific disease. When they do arise from such causes, there are usually one or two glands affected; but here there is a general glandular enlargement in the whole groin, all the glands and the intervening cellular tissue being affected. Such a bubo frequently follows any little point of irritation or any unusual demand upon the system, such as a long walk, especially in persons of a broken-down constitution. On examining this patient closely, we find that he has an inverted toe-nail, which is doubtless the primary cause of his trouble, as it is amply sufficient to account for it; we will cure this, and will probably at the same time cure the bubo.

CONTUSION OF RIBS.

Case III.—You examine cases of injury to the ribs, where there is a suspected fracture, by placing one hand on the sternal and the other on the dorsal extremity of the ribs, and pressing them together. If there is fracture you will produce pain and crepitus; but you should remember that there is often as much pain associated with bruising of the periosteal or perichondrial coverings of the ribs or of their cartilages as with fracture. The treatment is the same in both cases. Strips of sticking-plaster should be applied, one over the other, and running around the side of the chest from the spine to the sternum, so as to secure complete rest of the affected side.

(Cases of gonorrhœal bubo and hydrocele were shown to the class and were operated upon.)

PHILADELPHIA HOSPITAL.

SERVICE OF PROF. H. C. WOOD.

Reported by Dr. JOHN M. RADEBAUGH, Resident Physician.

SUDDEN DEATH IN ACUTE RHEUMATISM FROM RUPTURE OF A SMALL ANEURISM INTO THE PERICARDIUM.

W. O'B., æt. 40, Ireland, entered the medical ward May 20, 1875, late in the afternoon. He complained of pain in the knees, elbows, and phalangeal joints of the front and middle fingers of the left hand. He had suffered with these pains for two weeks previous, but had never, until that time, had any symptoms of rheumatism.

May 30, 1875, A.M.—On auscultation, a distinct murmur was heard with the first sound of the heart, which was loud and rough, and simultaneously a rough friction-like sound. Pulse was 130. At 7.30 P.M. he was comfortable. About 9.45, patient called nurse for a drink of water. Immediately after he threw up his hands, screamed twice, and was dead.

Post-mortem examination showed lungs healthy, but on the diaphragmatic pleura of the right side large fungus-like projections of false membrane. The pericardium was filled with a black clot, which completely surrounded the heart. There was an aneurism of the aorta, of moderate size, not sacculated, within the pericardium, and a small point of rupture just at the attachment of the pericardium. There was no peri- or endocarditis, and valves were normal. The ventricles were much hypertrophied.

TRANSLATIONS.

ON THE EFFECT OF DIRECT FARADIZATION OF THE VENTRICLES OF THE DOG'S HEART (A. Vulpian: *Centralblatt für Chirurgie*, No. 15, 1875).—In these experiments Vulpian thrust needles into the heart, either through the walls of the thorax or directly into the substance of the heart, after providing for artificial respiration and opening the thoracic cavity. These needles were then connected with the poles of the electrical apparatus and powerful induced currents passed through them. There occurred immediately, even when the needles were inserted only into the right side of the heart, active muscular tremblings in both ventricles, which occurred at various points, lasted four or five minutes, and then passed into mere twitching of fibres. After a period of three or four minutes more, the ventricles passed into diastolic quiet.

The same results were seen when the induced current was allowed to flow but for one or two seconds, or when, for instance, the electrodes were placed upon the heart and at once removed. No changes in the phenomena were noticed when the animals, previous to the transmission of the current, were brought under the influence of chloral or woorara.

After the cessation of the twitching of the fibres and the appearance of diastolic rest, the muscular tissue of the heart could no longer be excited by direct or reflex irritations.

Since these results of faradization were not changed by section of the pneumogastric nerves, nor by the previous administration of atropine, which is supposed to paralyze the terminations of the vagus in the heart itself, Vulpian concludes that the action of the current is exclusively upon the muscle of the heart.

Similar results were given when but one electrode was thrust into the heart, the other being allowed to rest upon some portion of the skin.

Only when feeble currents are employed are these symptoms transitory, followed by a return of the normal actions of the heart.

The observer, therefore, thinks that this electrical irritation gives rise to a kind of spasm of the muscle of the ventricles, by which they are prevented responding with rhythmical contractions to motor impulses which they receive from the cardiac ganglia. The spasmodic trembling which occurs most probably exhausts with rapidity the irritability of the muscular tissue of the organ. When the spasm ceases, the ventricles are no longer in a condition to be restored to activity by the nervous impulse, and therefore a total and final cessation of cardiac movement occurs. The knowledge that a fatal result to the dog follows these experiments must, at all events, arouse a dread that similar consequences might be met with in man. Since S. Mayer has also reached virtually the same conclusion, until further experience has been had it must be regarded as unjustifiable to endeavor to arouse the heart to action, in cases of sudden and alarming syncope, by electro-puncture, the use of which has been advised by some authorities.

W. A.

COMPRESSION OF THE AORTA IN GRAVE HEMORRHAGES FOLLOWING ACCOUCHEMENT.—In a letter to the *Bull. Gén. de Thérap.*, May 15, Dr. Berenger-Féraud recounts the following case:

He attended, in November, 1863, with Dr. Demarquay, a primipara in whom labor was rendered difficult by the disproportion between the maternal organs and the fœtus. Delivery was effected with the aid of the forceps, the child being born alive and in good condition, but a slight laceration of the perineum resulting in the mother. A few minutes later, while Dr. B. was examin-

ing the wounded perineum, he observed a sudden gush of blood from the vagina. The jet was nearly two-thirds of an inch in diameter. In less than six seconds it furnished between four and five pints of blood. As quick as thought the doctor leaped to the side of the patient's bed, tore off the clothes, and applied his hand firmly as a compressor over the umbilical region, forcing the aorta against the vertebral column. Dr. Demarquay, who was at the other side of the room, hastened to the patient, and arrived in time to confirm Dr. B.'s impression as regarded the size of the blood-jet. Having ascertained that the manual pressure controlled the hemorrhage, Drs. B. and D. practised friction upon the abdomen in order to contract the uterus, which was flaccid and relaxed. At the end of about ten minutes the uterus had recovered its tonicity and was contracted; compression was then suspended without recurrence of hemorrhage.

The amount of blood lost even in the brief interval before compression could be made was very large, and the patient showed all the symptoms usual after severe hemorrhage. No other means, says Dr. B., would have availed in this case. Tamponing the vagina would have cost the life of the patient by internal hemorrhage, since the uterus in its uncontracted condition would have contained a clot of at least four quarts before offering sufficient resistance to oppose the escape of blood. Neither external nor internal manipulation, nor the injection of styptics, could have been practised in anything like time to save the patient's life. X.

A CASE OF GASTRO-PULMONIC FISTULA FOLLOWING PERFORATION BY GASTRIC ULCER.—Inlinsberger communicates a case of this kind to the *Berlin. Klin. Wochenschr.*, 1874, No. 51. The diagnosis was made during life, as the very offensive sputa, in part fluid and in part muco-purulent, contained fragments of food, and, in addition, after each expectoration the previously prominent epigastrium became flattened.

The communication between stomach and lungs was attained in the following manner: the pyloric portion of the stomach was adherent to the liver near the suspensory ligament; a large opening existed in the posterior wall of the pylorus, above which was situated a cavity the size of the fist, filled with air and putrid matter. The walls of this cavity were formed in front and to the right by the chest-walls, below by the liver, to the left by the stomach, above and behind by the diaphragm. The latter was adherent to the pleura and lung, and presented an opening similar to the one leading into the stomach. The bronchia, opening into this cavity, conveyed the contents of the stomach into the trachea. Several tumors were found in the stomach, some of which were just breaking down into ulcers. X.

CROTON-CHLORAL IN DISEASES OF CHILDREN AS COMPARED WITH CHLORAL-HYDRATE.—Bouchut (*Centralbl.*; from *Gaz. Méd. des Hôpitaux*) is inclined, from his experience with croton-chloral, to attribute to this drug only trifling results, compared with those obtained from chloral-hydrate. While the latter in doses of forty to sixty grains will produce such perfect anæsthesia that abscesses may be opened and teeth extracted without pain, croton-chloral, even in drachm doses, scarcely causes sound sleep. The single advantage possessed by croton-chloral is its more agreeable taste. Bouchut has compared both remedies in chorea of children, and gives chloral-hydrate decidedly the preference. (According to Liebreich, croton-chloral, the taste of which is intensely bitter, acts chiefly upon the nerves of the head. In a solution in water of two scruples to six ounces, given in dessertspoonful doses every two hours, stubborn hyperæsthesia of the trigeminus has been cured in many cases and relieved in others.) SATURDAY, JUNE 19, 1875.

EDITORIAL.

TRANSFUSION.

PROF. MOSLER, of Greifswald, has recently reported in the *Berliner Klinische Wochenschrift* (May 17) the details of a case in which a woman who had for some hours lain pulseless and unconscious from intestinal hemorrhage due to typhoid fever was immediately and permanently revived by transfusion practised into her radial artery. Defibrinated blood from a healthy man was used. This is said to be one out of four cases, and the second successful one, in which transfusion has been used in the hemorrhage of enteric fever. There is one point in the case to which we desire to call especial attention. Prof. Mosler performed the operation in the unusual way employed, avowedly to avoid the risk of distending and thereby paralyzing an excessively weak right ventricle. Several cases abroad have proved instantaneously fatal from cardiac paralysis, evidently simply the result of over-distention of a right heart already scarcely able to fulfil its duties. One of the most terribly dramatic scenes we ever saw owed its chief interest to the same misfortune. The patient, a little French boy, in a foreign clime, pale and waxy from advanced leucocythæmia, surrounded by doctors, sat up in bed with an expression of mortal terror as he watched the preparations for the operation: screaming when the trifling incision was made; outwardly calm, but panting, with nostrils distended, as the syringe was introduced into the canula. Suddenly, as the piston went up, a frightful deadly pallor, a look of

mortal agony, a start and a cry, with upthrown arms, "Mon Dieu ! je vais mourir !" a gasp, a shudder, a heavy fall back upon the pillows, and the life was ended.

In this case, at the autopsy, the cardiac walls were found to be thin, and the muscles degenerated, whilst a large pericardial effusion added to the heart's embarrassment. As there was no reason for suspecting any entrance of air into the veins, the death was evidently wrought out in the manner described.

VENTILATION IN ZOOLOGICAL GARDENS.

IN the London Zoological Gardens five-sixths of the monkeys are said to have died in one month,—largely, as was pointed out by Dr. Neil Arnott, from improper ventilation. In our own garden the keepers attribute the very great success which has attended the acclimating of the giraffes to the extreme care given to the ventilation of the house. In New York, it is stated, the whole herd died during the winter; but here, out of six, four have been saved, and of those which died, one apparently received fatal injury on the voyage. The keepers of animals clearly recognize what keepers of men sometimes forget,—that good ventilation implies not merely sufficient changing of air, but also avoidance of draughts. This is particularly true of the camelopard: the same anatomical character that made Charles Dickens affirm that when he first tasted a sherry cobbler he wished he was a giraffe, renders this animal especially liable to fatal sore throat.

VIVISECTION.—The Home Secretary having stated that it is the intention of the Government to issue a small Royal Commission to make inquiries about vivisection, so called, "in order that they may have full information before they attempt to legislate on the subject," both of the bills to regulate the practice of vivisection in the British Islands, of which we recently spoke, are to be withdrawn. This solution of the matter appears to us a very fair one, and it seems not too much to hope for a fair, candid, and authoritative statement of the facts of the case. The profession may well court investigation.

THE "venerable Dr. Bullard," of New Haven, it is said, has been the high-priest at Hymen's fruition on over one thousand occasions. It is affirmed that the youth and maidens are "to hold a grand reunion and picnic" at his residence. For parents and children to hold a grand reunion would be suggestive; but the toast of the occasion will, we sup-

pose, be "The tie that binds us—Dr. Bullard, our common deliverer." Young men and maidens will share their common memories as they stroll over the lawn or whirl in the giddy mazes of the dance.

DR. S. WEIR MITCHELL has been elected Trustee of the University of Pennsylvania, with, of course, a special regard to the Medical Department. "Lesser than Macbeth, and greater. Thou shalt get kings, though thou be none."

ACCORDING to one of our exchanges, it has been found that invalids can be transported by rail with the greatest comfort in hammocks swinging from the ceiling of the car.

DR. GIBSON MAHON, of this city, was sentenced on the 11th instant to seven years' imprisonment at hard labor and to pay a fine of five hundred dollars for producing an abortion. Dr. Perpente is still in prison, awaiting the result of a motion for a new trial.

M. CALMETTE has demonstrated that the position of the arm affects most extraordinarily the sphygmograph: when the arm is held vertically the exact tracing of aortic insufficiency is obtained.

CORRESPONDENCE.

PENNSYLVANIA STATE MEDICAL SOCIETY.

POTTSVILLE, June 12, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

THE occasion of the Twenty-sixth Annual Meeting of the Pennsylvania State Medical Society will be long remembered, not only by reason of the large number of delegates present, but also on account of the peculiarly satisfactory manner in which the business and pleasures of the occasion were managed. Over one hundred and thirty delegates registered in the course of the session,—a larger number than ever before met together in our State convention.

The meeting was called to order by President Washington L. Atlee, at four o'clock, Wednesday, and after a prayer by Dr. Traill Green, of Easton, the address of welcome was made by Dr. A. H. Halberstadt, Chairman of the Committee of Arrangements. After the usual congratulatory remarks, Dr. H. referred to the often-discussed subject, "the advancement of the medical profession to that high position which their vocation would seem to demand, but which legislation has as yet failed to obtain." The remedy suggested by Dr. H. as the only one by which this can ever be accomplished would require of the student of medicine, before beginning its study, certain literary qualifications without which he dare not lay claim to the influence which every physi-

cian should command; and after this a full three-years' course of study, instead of the two five-months' courses now exacted of him. Such a course was found to be universally popular with the numerous members of the profession met at Pottsville, so that it can no longer be said that the people of Pennsylvania at least are not ready for this reform.

After the transaction of some routine business, written communications were called for, and the Secretary, Dr. Atkinson, read a paper by Dr. O. H. Allis, of Philadelphia, describing his apparatus for the inhalation of ether, already known to the readers of the *Medical Times*. The President, Dr. W. L. Atlee, made some remarks highly approving the apparatus. By its means he had become able to use pure ether in the performance of surgical operations, instead of the mixture of ether and chloroform previously used on account of the excitement ordinarily induced in the administration of ether.

Dr. Levis, of Philadelphia, did not like this or any other special apparatus for the inhalation of ether. In his experience he had found it uncleanly, as well as liable to injure the face of the patient through compression by the wire rim, and in one instance the patient had knocked it from the hand of the etherizer to the other side of the room.

Dr. Keyser, of Philadelphia, concurred in Dr. L.'s remarks; but President Atlee said these objections ought not to be ascribed to the apparatus, but lay in a want of care on the part of the operator.

At the conclusion of the session on Thursday afternoon, Dr. Allis, who was not present when the paper was read, administered ether by his apparatus in the presence of the Convention, and in four and a half minutes had so far completed the etherization as to make it evident that in at most a minute more the man would have been completely etherized.

Dr. John T. Carpenter, of Pottsville, exhibited the results of an exsection of the elbow-joint, in the arm of his brother, a bright lad of about eighteen years, who had accidentally shot himself in the past winter. The result was a truly remarkable one. All the motions of the joint were complete, and there was considerable strength in the arm, a chair being lifted with facility some distance from the floor. Indeed, the doctor informed us that the strength of the arm had diminished in the past month in consequence of the lad's playing baseball and otherwise using the arm in an excessive degree.

Dr. Keyser, of Philadelphia, read the results of some forty-seven cases of cataract operated upon by him by Graefe's peripheric linear method, in which a better percentage of results was obtained than where iridectomy was not performed, although in some respects this operation is not to be preferred. Dr. K. also explained the method of recording results.

In the evening, at eight, the Convention listened to the address of the President on "Old Physic and Young Physic," which consisted in a comparison of the practice of the present day with that of thirty years ago. In the contrast drawn, at times "Old Physic" appeared to

advantage, and at times "Young Physic." The chief misfortune of "Young Physic" consisted in his neglect of blood-letting, which was shown to have often been of signal advantage in the hands of "Old Physic" for the alleviation of symptoms; while in the free use of cold water and diluent drinks in fever, and the progress made in the knowledge and treatment of diseases of women, "Young Physic" was decidedly in the ascendant. The influence of the dress of women of to-day in producing their diseases was dwelt upon, and congratulations were made upon the successful establishment of a Woman's Medical College.

After the conclusion of the address, the delegates repaired to the house of Dr. Halberstadt, where they were most handsomely "received." The spacious parlors of the doctor were crowded, and the hum of voices busy in the exchange of greeting and sentiment only ceased at a late hour as the company separated. We can scarcely recall an occasion where the enjoyment seemed more thorough.

SECOND DAY.—The chief events of the morning session were the reading of the papers on Medicine and Surgery, the former by Dr. William Pepper, and the latter by Dr. Richard Levis, and an excellent report on Hygiene, by Dr. Lee, of Philadelphia. The address of Dr. Pepper, which made a most favorable impression, consisted in a review of diseases added to the nosology in recent years, and of the therapeutic advances in the same period, including the exhibition of instruments recently made available in therapeutics, among which were apparatus for transfusion and for deeply injecting such organs as the lungs, clinical thermometers, etc.

Dr. Levis's paper was upon fractures of the lower end of the radius, in the course of which he stated that the most usual fracture was a transverse one one-fourth to three-fourths of an inch above the lower end of the bone. He also showed that the existence of the fracture usually described as Barton's, the essential feature of which was a chipping off of a fragment of bone communicating with the joint, was exceedingly rare, if ever occurring. He concluded by exhibiting an ingenious apparatus for producing extension, which he considered essential in the treatment of fractures of this end of the radius.

Dr. Lee's address, after a graceful tribute to Hygeia, included an account of the contamination of water and milk, and its influence on the production of typhoid fever by fecal excreta, confirmed by the history of several epidemics. The importance of ventilation and the best means of securing it were considered. The method of Mr. Barker, of Germantown, as adopted in the new University buildings, was described and illustrated by diagram.

Dr. Lee concluded by offering a resolution to the effect that a committee of three be appointed to memorialize the Legislature and to take such other steps as will secure the appointment of a State Board of Health. Drs. Atkinson, of Philadelphia, Traill Green, of Easton, and Orth, of Harrisburg, were appointed.

In the afternoon session Dr. A. P. Carr, of St. Clair,

Schuylkill County, exhibited a miner who had suffered fracture of the skull, loss of an eye, and fracture of the thigh by the premature explosion of a blast. The skull had been trephined with good results.

Dr. C. also exhibited some of the calculi from forty-two cases of lithotomy performed by himself, of which only one was fatal.

Appropriate resolutions of regret and condolence with regard to the late Dr. D. Francis Condie were read by Dr. Nebinger, of Philadelphia, and unanimously adopted.

Dr. R. L. Sibbett, of Cumberland, read the report of the committee appointed at the last meeting of the State Association to secure proper legislation to protect the people against incompetent practitioners of medicine, surgery, and obstetrics, which had resulted successfully. Considerable discussion followed as to the best means of carrying out this law, participated in by Drs. E. A. Wood, of Pittsburg, and Roebuck, of Lancaster, members of the State Senate, and the matter was finally referred to the several County Medical Societies, with the request that they appoint a committee of three to secure the enforcement of the law.

Dr. Curwen, of Harrisburg, then read his report on "Mental Disorders." The general principle which should guide us in the detection of insanity is the comparison of the individual with his former self, rather than with any other individual. The general causes only of insanity were dwelt upon, among which the present vicious system of education received some attention. The address made a decided impression, and excited some discussion, the result of which was a resolution to the effect that Dr. Curwen be requested to furnish that portion of his address relating to the subject of education to State Superintendent Wickersham, for publication in the *School Journal*, and to the Educational Publication Committee of Philadelphia.

Five thousand copies of the Code of Ethics of the Society were ordered printed for general distribution.

Dr. Deshler, delegate from the New Jersey State Medical Society, being introduced by Dr. Halberstadt, made a most pleasing address, which was a pithy review of the proceedings, which he proposed to make to his Society on returning, and many parts of which he thought would be received with pleasure and surprise by his friends in New Jersey.

Dr. Turnbull, of Philadelphia, read a paper on "Disorders of the Eustachian Tube," and recommended suitable treatment.

Dr. Curwen, of Harrisburg, offered the following important resolution, which was adopted:

"Resolved, That a committee of eight members of this Society be appointed to prepare a memorial to the Legislature in favor of a hospital for the insane of the Counties of Berks, Bucks, Chester, Delaware, Lehigh, Montgomery, and Northampton, and to urge the passage of a law to establish the same."

Drs. Curwen, of Harrisburg, P. B. Brenning, of Northampton, W. M. Weidman, of Berks, Gilbert McCoy, of Bucks, H. Corson, of Montgomery, I. Price, of Chester,

L. Fussell, of Delaware, and E. G. Martin, of Lehigh, were appointed the committee.

Then followed a long discussion on the causation of typhoid fever, which amounted to a reiteration of the history of the numerous late epidemics, with which the readers of medical journals are all familiar.

The report of the Nominating Committee, which was adopted, provided for the following officers for the next meeting, to be held in Philadelphia on the last Wednesday in May, 1876:

President, Dr. Crawford Irwin, of Blair County.

Vice-Presidents, Drs. Andrew Nebinger, Philadelphia; A. H. Halberstadt, Schuylkill; R. L. Sibbett, Cumberland; and J. I. Ross, Clarion.

Corresponding Secretary, Dr. Thomas M. Drysdale, Philadelphia.

Permanent Secretary, Dr. William B. Atkinson, Philadelphia.

Recording Secretary, Dr. James Tyson, Philadelphia.

Treasurer, Dr. Benjamin Lee, Philadelphia.

Committee of Publication, Drs. William B. Atkinson, J. G. Stetler, Benjamin Lee, T. M. Drysdale, James Tyson, Albert Fricke, of Philadelphia, and Charles McIntire, of Northampton.

The event of the evening was a banquet given by the Schuylkill County Medical Society, at Union Hall, where strains of music, the din of voices, and tinkle of glasses combined to produce an occasion long to be remembered by delegates. The usual toasts were read, and were responded to by Drs. E. A. Wood, Atkinson, Nebinger, Allis, Messrs. Harris and Schoeffer, of the Reading Coal and Iron Company, Rev. Mr. Smiley, and others.

I will not detain you by an account of the delightful excursion of Friday, through the mining district, by the courtesy of the Philadelphia and Reading Railroad Company, and participated in by an unusually large number of delegates; suffice it that it was one joyous gala-day from early morning until evening, when the delegates were transferred to the main line of the Philadelphia and Reading Railroad, and distributed to their scattered homes.

X.

MASSANETTA SPRINGS.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—I desire to call attention to the value of the water of Massanetta Springs in chronic malarial poisoning. The springs, commonly called Taylor Springs, are situated four miles from Harrisonburg, near the peaks of the Massanetta mountains, in the County of Rockingham, in the Valley of Virginia.

It may surprise some of your readers to learn that there is a mineral spring which is accredited with the virtue of curing any form of chronic intermittent malarial disease, however debilitating, stubborn, or chronic. I am, however, really persuaded of this fact after a most careful investigation for many years, which has also shown me the value of this water in organic disease of the kidneys. This spring has been visited for

a hundred years by persons afflicted with what they deemed incurable agues. The tradition and belief in this county is universal that it has never failed to relieve every case. I have carefully investigated this tradition through such sources as the Hon. Judge Daniel Smith of the Court of Appeals of Virginia, Gen. Samuel Lewis, Hon. John F. Lewis, of the U. S. Senate, who lived all their lives close neighbors to the spring; I have sought out all the previous owners of the property and hotel proprietors of the springs. The oldest neighbors, some of them octogenarians, all assert from personal observation the restoration of health which has been afforded, and their belief is fully supported by medical evidence, very many of the physicians of this county having verified this belief in their own practice by sending their patients to the spring and watching the result. Among them I may mention Drs. Gordon Williams, Webb, Kyle, Minor, Kemper, and others. I have myself over and again seen the following results: most persons have only one chill after drinking the water at the spring; some have none; the lesser number have two; very few have three chills. Nor is it strange when you consider that, according to the late Dr. Rogers, of the University of Virginia, the water contains arsenicum, iodine, chlorine, potassium, sodium, magnesium, calcium, iron, free nitrogen and carbonic acid gases.

I will not occupy space by reporting individual testimony, excepting that of Dr. F. Asbury Effinger, who practised medicine in the Brazos Swamps of Texas,—as rank in malarias as any place in the country. He says, "I had chills for several years, and began to despair of recovery. I repaired to the Massanetta Springs, and soon recovered. I practised medicine for fifteen years afterwards on the Brazos River, and never had another chill."

Col. De Neale states that "he saw thirty-nine Confederate soldiers with ague put in hospital at the Massanetta Springs during the late war at one time, and in a fortnight every one was well."

The water is delicious, very soft, and wholly unirritating; a drink pleasant in all its effects upon the skin, kidneys, liver, stomach, and bowels.

There is a great deal of evidence to establish the value of the remedy in organic kidney-disease, and evidence of much weight, but I will give an account of its history in kidney-diseases at some future day.

Respectfully,

B. CHRISMAN, M.D.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, APRIL 8, 1875.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

Epithelioma of the lip.

DR. C. B. NANCREDE presented two specimens of this affection. The patient from whom the first was removed, E. B., 78 years of age, first noticed about

six months ago a hard lump on the left side of the upper lip. He has been a great smoker, using a clay pipe. About four months ago ulceration commenced, rapidly progressing, and producing an excavated, deep, painful ulcer, with indurated edges, in size about that of a nickel cent.

It had been cauterized frequently by his physician, with nitrate of silver, which had only aggravated the trouble. The patient's general health was excellent, with no arcus senilis, or atheroma of the arteries. His heart-sounds were strong and normal, his hair luxuriant. There was nothing of special interest about the operation, which has proved, thus far, successful, it having been performed the 2d of February, 1875.

The second case presented by Dr. N. was removed from W. B., aged 78 years, who first noticed about six months ago a small wart-like projection on the left side of the lower lip, which grew rapidly, soon ulcerating and occasionally throwing small pieces off in the form of sloughs. No treatment was attempted till he came to him, when he found a mass, about the size of a chestnut, occupying a third of the free surface of the lip, ulcerated and covered with scabs.

When first seen, on the 22d of February, 1875, its removal by the knife was advised, which operation he performed two days later, with success so far.

There is one point of interest in connection with the first case,—viz., the occurrence of true epithelioma on the upper lip, where rodent ulcer is much the more frequent.

Dr. N. desired to hear some expression of members as to the origin of epithelioma, whether it be a hypertrophy of granular tissue, a return of the follicles to the foetal state, or whether the more recent view of Köster of the endothelial origin is to be preferred.

Dr. JAMES TYSON said he could not speak from personal investigation of specimens bearing upon this question, but, from a somewhat careful examination of the observations of others, he felt that while at first thought the formation of cylinders was best explained by their origin in re-solidification of the sebaceous follicles,—a return to their foetal state, as Dr. Nancrede expressed it,—he did not see anything in the way of admitting also Köster's view with regard to the extension of the epithelial protrusions along the interior of the lymphatic vessels, and thus allowing both modes of origin. Some of the members were probably familiar with some comparatively recent observations by Dr. Woodward, of the Army Medical Museum, which tend to support Köster's views.

Dr. R. M. BERTOLET said that the theory of an endothelial origin of epithelioma, as advanced by Köster, was very enticing, and that formerly, having used the nitrate-of-silver staining in a number of fresh growths, he was inclined to adopt this view, but, upon closer investigation, he found it inadequate to account for all of the alterations ordinarily met with in this class of tumors. The glandular apparatus of the skin in cases of epithelioma are so manifestly hypertrophied, there is, evidently, such an active proliferation of the epithelial lining of the sebaceous and sweat glands, that it was impossible to ignore the fact that they performed an important, if not the chief, rôle in the origin of these growths. No doubt the lymphatics served as convenient spaces for the ingrowing cancrioid tubuli, and the endothelia then became involved secondarily.

When we examine the analogous cylinder-growths upon the mucous membrane, there is no question but that primarily the mucous glands are solely involved; especially where the new growth assumes, as so often happens, the habitus of an adenoma. Further, we find that the metastatic growths preserve the type of the glandular structure whence the primary growth has sprung; and thus it happens that we come to find, as has been so aptly stated, rectum in the liver.

Owing to the comparative infrequency of metastases into distant organs, the same cannot be as positively asserted of epithelioma of the skin; yet when these secondary growths shall have been more fully studied, he predicted, it would prove that they also presented an imprint of a glandular and not an endothelial tissue.

Abscess of the lung.

Dr. JOHN GUITÉRAS presented the specimen, from F. W., æt. 26; colored. Was admitted on the 30th of March into the wards of Blockley Hospital. His friends stated to the nurse that he had been ailing with some chest-trouble for about two years.

On the 29th, the day before admission, he had a very severe chill, and on the evening of the 30th his temperature was 103°. On the 31st, morning temperature 100°; evening temperature 101°. On the 1st, morning temperature 99½°, pulse 105; evening temperature 100°. On the 2d, morning temperature 97°, pulse 84; evening temperature 98½°, pulse 80. This day Dr. G. saw him for the first time, and found him very drowsy, so that the only information he could obtain from him was that he had been ailing for two months, but had only become very ill the last week. His skin was cold and clammy. He had commenced to expectorate large amounts of a brown and extremely fetid fluid.

The respiratory movements were impaired, and the vocal fremitus was increased throughout the right side. Percussion over the upper lobe in front elicited a tympanitic, low-pitched resonance at the apex; farther down and towards the axilla the note became higher pitched, but more metallic. Complete dulness was developed over the whole right lung posteriorly. Auscultation revealed a loud, harsh inspiratory sound, with a prolonged expiration at the apex. Towards the axilla the sounds became fainter, until they were absolutely lost in the axillary line. Here they were substituted by a crackling, which sounded sometimes like a large moist râle, at others like a friction-sound; it had at the time no cavernous or metallic echo. Dr. G. imagined that there was very little if any air moving in and out of this cavity at the time of his examination. Posteriorly there was well-marked bronchial breathing. The left lung gave evidences of vicarious function throughout.

Not finding any evidences of chronic disease of the lungs, he thought that the breaking down of the pulmonary tissue must have been acute,—either abscess or gangrene of the lung.

The diagnosis of the physical condition—viz., a large cavity near the anterior surface, surrounded above by lung-tissue pervious to air, and below by consolidated tissue—was confirmed by the autopsy. On the 3d, morning temperature 97½°, pulse 90; evening temperature 99½°, pulse 96. On the 4th, morning temperature 99½°, pulse 99, respiration 36; evening temperature 100°. On the 5th, morning temperature 97°, pulse 136, respiration 60; evening temperature 98½°. At the time of death, 8 P.M., the temperature was 96½°.

Autopsy.—The subject was a very muscular and well-nourished negro. The upper lobe of the right lung was firmly adherent to the chest-walls. The lower lobe was separated from them by a small quantity of fluid. The diaphragmatic pleuræ were adherent. The left lung was simply congested and œdematous, almost to the extent of splenization. The right lung presented in the upper half of the superior lobe, and towards the antero-lateral surface, a large cavity occupying about one-half the volume of the lobe. Its walls presented excavations in different directions, and they were lined in some places with a smooth membrane; at others, ragged pieces were seen floating from the surface. Evidently the extension of the necrobiotic process had been arrested in some places, though the cavity still contained a considerable amount of the brownish fluid that he expectorated

so freely. The apex of the right lung was still pervious to air; but around the cavity and elsewhere through the lobe the tissue was in a condition of purulent infiltration, readily breaking down under the finger. The lower lobe was in the stage of red hepatization. Nowhere was there any evidence of chronic inflammatory change of the pulmonary tissue, or of deposit of caseous matter.

The specimen answers very closely to the descriptions given by authors, both of gangrene and abscess after the process of destruction is arrested. Dr. G. left it with the Society to decide whether he was right in entirely rejecting any chronic element from the process of destruction in the present case.

The PRESIDENT said the patient was in his wards at the Philadelphia Hospital, but that, on account of unavoidable absence extending over a few days, he did not have an opportunity to examine him. But he thought from the description of the lesions that at least we must admit two separate stages of disease, or perhaps two diseases which had originated at different periods. He thought it scarcely possible that the acute inflammatory condition of the lower lobe, and the lower portion of the upper lobe surrounding the abscess, could be of the same date as that part of the disease which had led to the production of the anfractuous cavity with smooth lining membrane. The President remarked that an abscess (cavity?) in the lung could exist for some time, and that the lung could be attacked by an acute destructive process leading to gangrene and purulent infiltration of the tissue surrounding the cavity; that this was a more reasonable supposition than one which explained the condition by a single process which should have passed so rapidly through acute inflammation to acute gangrene of the lung, while the appearances of the cavity and the adhesions of the upper lobe to the pleura would suggest some morbid action of long standing.

Dr. GUITÉRAS said there was no disease whatever of the opposite apex, and he had never seen a case in which chronic disease had advanced so far on one side without being attended by some disease of the other lung. Further, the patient was what might be called a typically-healthy and remarkably well-developed negro, so far as the external evidences of health were concerned.

The PRESIDENT replied that the points raised are those which give to the case its unusual interest, and perhaps render uncertain the exact determination of the stages of development of the lesion. It is to be regretted that there had been no opportunity for previous examination of the lung. It is to be remembered, however, that it is not uncommon to see cases of chronic cavity in one lung, the subjects of which are in apparently good condition (though liable to intercurrent disease, or sudden outbreak of tuberculous deposition), and that in such cases it is not rare for the disease to be limited to one apex for a long time.

Tubercular laryngitis.

Dr. BERTOLET presented three specimens of tubercular laryngitis, which will be found reported in another column in the current number of the *Times*.

Dilated heart; pleuritic effusion in a patient who had yellow fever two years previous to death.

Dr. JOHN H. PACKARD read the following history of the case:

"Mr. R., æt. 63, first came under my care in October, 1874, on account of asthmatic trouble, with rapid, enfeebled, and irregular action of the heart. He had never been in perfectly good health since an attack of yellow fever, according to his statement a very severe one, which he had had, some two or three years ago, when in Mobile. Some years before that he had had

some form of ophthalmia, by which, or, in his opinion, by the severe treatment adopted, the sight of both his eyes had been totally lost.

"The symptoms above mentioned were in a great degree relieved by the use of tonics and digitalis; but in February they recurred, and proved less amenable to treatment. On the 1st of March he was attacked with congestion of the lungs and hæmoptysis. The right lung was more seriously affected than the left. This congestion passed off entirely within a week, but the marked debility which had attended it remained, and steadily increased until his death, March 31.

"During the continuance of this congestion, and to some degree after it had subsided, there was dulness on percussion over the right back, and the liver could be plainly felt extending below the ribs, its surface being nodulated. The urine was albuminous, but not highly so. A week or more before his death, an anasarctous condition of the legs, which had been gradually increasing, suddenly became very marked; and during the last three days of his life gangrene began in the columna and tip of the nose.

"An autopsy was made, thirty hours after death, by Dr. John M. Keating. Body in ice; rigor mortis scarcely perceptible.

"In opening the thorax, the cartilages of the ribs were found very firmly ossified, so that they had to be sawn through. A large effusion of serum existed in the right pleura, perfectly limpid except in the neighborhood of an old adhesion posteriorly, where there was a long ragged flake of lymph. The lung was somewhat emphysematous above and in front, but below and posteriorly there was a focus of very marked congestion, a portion of the tissue sinking in water. In the left lung the same appearances existed, except that the congestion was less marked and seemed to be merely hypostatic. There was no effusion in the left pleura.

"The heart was very largely dilated, its tissue far advanced in fatty degeneration, its valves all healthy, as were also the large vessels. The auricles and ventricles were full of blood, liquid in the right cavities, softly clotted in the left.

"In the abdomen there was found a good deal of fat in the subperitoneal areolar tissue, extending along the suspensory ligament of the liver, which organ was roughened or finely nodulated on the surface, and seemed to be fatty. A curious arrangement of the gall-bladder was noticed; it was very long, full of fluid bile, and curled up around the anterior edge of the liver, so as to have its fundus directed towards the diaphragm.

"The omentum was strongly adherent to the underlying viscera, and numerous adhesions and slight deposits of lymph existed between the coils of intestine. Nothing abnormal was noticed in the condition of the alimentary canal. The pancreas was somewhat bulky, but not perceptibly diseased.

"The spleen was rather a small one, very firm, and of a dark plum-color on section.

"The kidneys were not enlarged, perhaps somewhat contracted; their surfaces were lobulated, and the section seemed to the naked eye to indicate cirrhosis.

"Portions of the spleen, liver, and kidneys were submitted to Dr. R. M. Bertolet for microscopical examination.

"The question as to the agency of the attack of yellow fever in inducing the pathological changes above recorded is one upon which those more accustomed to the study of purely medical disorders may be able to pronounce a ready judgment; to my own mind, the history the patient was able to give me seemed too vague and incomplete to permit me to do so.

"The chain of morbid conditions leading to death in this case seemed to be as follows: the dilated and fatty heart was of inadequate power to drive the blood

against the disadvantage of imperfect aeration in the emphysematous lung; upon the occurrence of congestion of the lung from a casual chilling of the cutaneous surface, the sluggish circulation aggravated it, and gave rise to dropsical effusion into the right pleural cavity, this being the side on which, from the position of his bed, he habitually lay; this condition mechanically hampered the action of the lung, and further embarrassed the weak heart, promoting the occurrence of slight ascites and anasarca; all these circumstances, with the imperfectly performed functions of the liver and kidneys, constituting a total of depression under which the muscular tissues of the heart failed altogether."

Dr. R. M. BERTOLET had made an examination of a small section of the heart, and found in a marked degree the fatty degeneration of its muscular structure. The cirrhosis of the liver and kidney had not yet reached the latter stages, but was present, as evidenced by a hypertrophy of the connective tissue about the blood-vessels, the Malpighian capsules, and the membrane of the tubules.

The PRESIDENT said the extent to which the liver and even the kidneys are implicated in yellow fever makes the condition of these organs, in cases where recovery has taken place, an interesting one. He thought that the characters of the disease were such that they need not lead necessarily to cirrhosis of these organs; while the frequent existence of emphysema of the lungs, fatty degeneration of the heart, and cirrhosis of the kidneys in cases where no yellow fever is previously present makes the question a very obscure one. He asked Dr. Bertolet whether he was aware of any facts bearing on the question of the liability of the kidneys and liver to organic disease subsequent to recovery from yellow fever.

Dr. BERTOLET replied that he had never had the opportunity of making a post-mortem examination in a case of yellow fever, and, although much had been written upon the subject, he felt that the pathology of the disease was still ill determined. He thought the condition of the liver and kidneys ordinarily met with in yellow fever by no means necessitated, and it was doubtful if they even favored, the development of cirrhosis in these organs. Fatty infiltration of a glandular tissue did not necessarily imply its destruction, nor is the atrophic liver always a resultant of a sclerotic process or so-called cirrhosis. Should we admit the occurrence of cirrhosis as a sequel of yellow fever, we must first carefully exclude all other causes of the same state, as alcohol, intermittent and other fevers, before we could be certain it was produced by yellow fever.

Intestinal obstruction caused by huge thrombus resulting from rupture of the abdominal aorta.

The PRESIDENT made a communication relative to a case of *intestinal obstruction* from an unusual cause. The patient was an old man, aged 82, who had long suffered with a right inguinal hernia. For some time before his last illness he complained of pain in that region. When seen first by Dr. M. Woods, his attending physician, he was complaining of considerable abdominal uneasiness, and there was obstinate constipation. This continued despite the use of large enemata and full doses of powerful cathartics. When first seen in consultation, there had been no fecal evacuation for at least ten days. There was frequent hiccough, but no actual vomiting. There had been, however, very little food taken during that time. The patient was delirious, and difficult to restrain. The pulse was frequent and small; the radial arteries very atheromatous. There was no hernia detectable in either groin. The abdomen was distended, and the walls enormously fatty, so that careful palpation was impossible. The amount of urine secreted was difficult to estimate, as it was passed in the bed. Digi-

tal examination of the rectum showed that this part of the bowel was clear. Attempts were made to give large injections by a syringe, which was found impossible. By employing hydrostatic pressure (gained by pouring water from a height of about six feet above the body through a flexible tube furnished with an olive-shaped end) about one and a half pints of water were forced into the bowel; when this escaped, it brought several pieces of hardened feces. It was again attempted, but it was impossible to make the bowel contain as much the second time, and no result was obtained. The diagnosis, therefore, was readily arrived at, notwithstanding the complication of the case with an old hernia, that there was some increasing obstruction low down in the bowel, and probably in the sigmoid flexure of the colon.

Death ensued forty-eight hours later, from exhaustion. At no time had the obstruction been so complete as to prevent the passage of some flatus.

At the post-mortem examination the right inguinal canal was found much dilated, but containing no hernia. The cause of obstruction was sought by following the intestines downwards from the stomach. There was no trouble in the course of the small intestine, which was, however, very unequally distended, some parts being very full, others almost empty, small, and compressed-looking. On reaching the descending colon, it was found to be strongly adherent to and much compressed by a large mass which occupied the left lumbar region. This mass was about nine inches long, four and a half inches wide, and three inches thick. On incision, it was found to be an enormous clot of blood, evidently of some duration, being blackish, firm, and infiltrating the fatty and cellular tissues of the part. The aorta was imbedded in this clot, and on discovering and laying open this vessel its walls were found in a state of such intense atheromatous degeneration that they had given way, and several ruptures had occurred in the inner and middle coats of the vessel. The huge clot above described was, therefore, in part a dissecting aneurism, and in part depended on the escape of blood through the adventitia infiltrating the surrounding cellular tissue. No distinct aneurismal sac could be detected. The obstruction of the intestine was entirely due to the pressure of this mass, and was most marked low down in the sigmoid flexure of the colon, thus agreeing closely with the seat as determined by previous examination.

REVIEWS AND BOOK NOTICES.

A PRACTICAL TREATISE ON DISEASES OF THE EYE. By HAYNES WALTON, F.R.C.S., Surgeon to St. Mary's Hospital, Surgeon-in-Charge of the Ophthalmic Department of the same, Lecturer on Ophthalmology, etc., etc. Third Edition, Re-written and Enlarged. In one large octavo vol., 1188 pages.

In commencing for critical review a book just entering upon its third edition, re-written and enlarged, which had been in its former editions "most favorably reviewed by some of the highest authorities in Great Britain, including a most extended, elaborate, and valuable one by Dr. Mackenzie, of Glasgow," one does so anticipating the pleasant duty of little else but favorable comment on its merits. At the very threshold, however, these anticipations are marred. In the otherwise fine plate representing a horizontal section of the eyeball (spoken of as vertical under the plate), the iris is represented as hanging free between the anterior and posterior chambers. It is now so well known that the iris is in contact with, and finds support for its pupillary margin on, the anterior capsule of the lens, that there seems no excuse for propagating an error like this by

pictorial representation. We are not told whether the plate is from an original drawing. We infer not, although no mention is made of its source, from the fact that the author distinctly states on page 809 that the "iris is in contact with the lens in the natural state."

After the table of contents, etc., we are greeted with an anatomical introduction of twelve pages, too short for the student of the anatomy of the eye, and not sufficiently minute to claim the attention of the ophthalmologist. The first four chapters are devoted to ophthalmic instruments, anæsthetics, eye-douches, and eye-shades. These general topics, which, very appropriately, begin the work, could as well have been placed in one chapter. In perusing them, we were pleased and instructed by the many practical suggestions and the terse and vigorous manner of expressing them.

The succeeding chapters from V. to XI. inclusive are respectively devoted to entozoa, diseases of the orbit, of the frontal sinus, tumors, protrusion of the eyeball, erectile and vascular tumors in association with the eye, and aneurism in connection with the eye. These chapters are exceptionally valuable, both because of the concise manner in which the author has stated his wide experience in the form of differential diagnosis, and the large number of illustrative cases he has culled from his practice. For the sake of the student, however, one cannot but think it had been better to have reserved these chapters, devoted to comparatively rare and obscure affections, until the less serious and far more frequently occurring diseases of the conjunctiva, cornea, iris, etc., had been treated.

In Chapter VI., p. 43, the author states that "*orbital cellulitis is one of the three varieties of erysipelas, the others being the cutaneous and cellulocutaneous.*" The italics are his own. He would probably have some difficulty in finding support for such statements, except in cases where the cellulitis of the orbit resulted from an extension of erysipelatous inflammation from the face or elsewhere to the orbital contents.

Chapter XII. has the somewhat euphonious title of "*Geometrical Optics.*" We cannot but regret that our author had not justified the use of this caption by a more thorough and complete treatment of optics as applied in ophthalmology.

Chapter XIII. is on the construction of spectacles.

Chapter XIV., on the ophthalmoscope. Decided preference is expressed for the ophthalmoscope of Coccus, while the far more excellent and convenient instruments of Loring and Knapp, of this country, are not even mentioned. Such a glaring omission is difficult to account for, except on the principle that no good thing can come out of Nazareth.

On p. 305, while treating of the normal aspect of the retina and optic disk, we find the statement that "little is to be seen of the *macula lutea* in the erect image," and the careful descriptions of Helmholtz, Coccus, and Liebreich are stigmatized as "*incongruous.*" Most observers would feel themselves at great loss were they not able to employ the magnified upright image in the study of pathological changes in and around the macula.

Chapter XVI. is devoted to the discussion of the paralytic affections of the eye, and is one of the most valuable chapters in the book. We regret that the space allotted us will not permit more extended notice of this satisfactory chapter, treating, as it does, of one of the most perplexing subjects to the oculist. Our author's experience corroborates that of most observers as to syphilis being the "commonest cause" of these ocular paralyses.

Chapter XVII. is upon ptosis, or falling of the upper lid. Why it should have been arbitrarily severed from its place among paralytic affections is not obvious. All operators will not agree with him as to the efficacy of

the removal of an ellipse of integument from the upper lid in overcoming the defect.

Chapter XVIII. is devoted to the consideration of the somewhat difficult subject of strabismus, which is rendered doubly confusing. After the careful study of paralytic affections of the muscles in the preceding chapter, one is surprised at being once more confronted by them under the head of strabismus. Our author has, we think, injudiciously adopted the old habit of classifying deviations of the visual axes from paralysis of antagonizing muscles with strabismus. Formerly all deviations from whatever cause were included under this term; but since the researches of Donders and Von Graefe it has come to be limited to that group of cases characterized *invariably* by the fixing of one eye upon the observed object, while the other deviates from its normal direction; the degree of movement in each being equal and normal, while all deviations depending upon paralysis or insufficiency from any cause, or mechanical obstruction to the movements of the eyeball, have been excluded and properly classified under their respective heads. It is to be regretted that in the work before us this course was not adopted. There is a wide difference between the paralytic deviations of the eyeball and true strabismus, as regards their etiology, symptoms, and treatment. Paralysis of the ocular muscles is usually but a symptom of some central or intra-cranial lesion of which it may be but a remaining evidence; while in strabismus we have to do with the eye alone. The treatment of ocular paralysis under this head has led our author into not a little confusion and conflict with accepted views of the ophthalmologist,—*e.g.*, in speaking of the period at which the squint begins, he asserts that "from early infancy eyes may lose their parallelism and turn inwards." On p. 370 he says, "I am myself quite satisfied that squint has existed in several children who were brought to me within the month, and therefore it is not unreasonable to suppose that the statements of the mothers to the effect that the squints were observed a few days after birth were correct." The observations of Donders, verified by those of numerous subsequent observers, place the usual commencement of squint at about the fifth year, or at the time children begin the continued use of their eyes for near work. The writer has seen a number of cases of squint occurring between the third and fifth years, but never earlier than the third year. Numerous examples of deviation have fallen under his notice, occurring at a more tender age, but they have, without exception, belonged outside the category of true strabismus; depending either upon some disturbance of innervation or opacities in the refracting media.

In the etiology of strabismus convergens, our author has strayed very widely from the generally accepted views, and it is here we find the key to the confusion characterizing his chapter on strabismus. He denies that strabismus is but a symptom of hypermetropia, as put forth by Donders, taking exception entirely to the validity of his reasoning. It would lead us too far to enter into the discussion of this question with the space allotted us. It is sufficient evidence, however, of the fallacy of his position that the views of Donders have been subjected to the most careful scrutiny, and his observations everywhere confirmed by other observers. It is the very rare exception to find strabismus convergens disassociated with hypermetropia.

The following is a fair example of our author's reasoning: "In vain have I been looking for squint with hypermetropia only,—that form of faulty refraction with good power of accommodation, in which the application of lenses will enable the squinter to see minute and distant bodies. I find, as a rule, that where hypermetropia is present with squint, loss of acuteness of vision is

more frequently associated with it than not. I am, therefore, disposed to attribute the deformity more to the impairment of sight than to the hypermetropia. . . . Where, in periodic squint with hypermetropia, some loss of acuteness of vision occurs, a convex lens enables the eye to right itself, I consider that such a result is as much due to the increase of the visual angle and enlargement of the object as to the hypermetropia being neutralized."

In the treatment of strabismus by operation our author, rightly, we think, prefers to incise the conjunctiva and sub-conjunctival tissue vertically over the attachment of the muscle, and securing the tendon over a blunt hook (he prefers a curved one without a bulbous extremity), and then severing its attachment close to the sclerotica. He strongly advises the use of the conjunctival suture, as being safer and reducing to a minimum the traces of the operation. In this country operators usually omit the suture, in order to modify the effect of the operation subsequently should the muscle have attached itself too far back. The author distinctly declares, in two places in this chapter, that the degree of deviation is a matter of no importance; that, however slight or great, the muscle must be entirely divided. It is true that nothing less than its perfect division and re-attachment at a point farther back on the globe will meet the requirements of the case, but it is equally true that the extent of the retraction of the muscle is largely under control by the amount of laceration in the sub-conjunctival tissue and capsule of Tenon, so that it is obviously of importance to know whether there is a deviation of but $1''$ or $4''$ to correct.

The amblyopia of the deviated eye is a well-known fact. Every one conversant practically with strabismus will have seen repeatedly the eye, before the operation practically blind, within a short time recover normal sharpness. Mr. Walton declares this improvement to be immediate.

In our own experience, while the improvement has been manifest in twenty-four or forty-eight hours, it has been only after the lapse of a few weeks or, in some cases, months before the normal sharpness was regained. As might have been anticipated from his views upon the causation of strabismus convergens, he makes but small account of the correction of the hypermetropia, simply stating that any existing optical defect should be corrected, but follows immediately with the remark that relapses are due to disuse of the eye. He has had but four cases of relapse in his private practice, while he does not remember any in his "public operations." "There can be little doubt," he says, "that in many of the supposed cases of recurrence the operation has never been completely done."

In diverging strabismus he again takes exception to the explanations of Donders. On page 400 it is stated, "I do not believe that the form of the myopic eye interferes with its movements." Believing the changes are too small to impede seriously its movements in the orbit or to change the relative action of the muscles, he remarks, page 401, "I admit, in a general acceptance, the statement about the insufficiency of the rectus muscles, but it must be remembered that the word *insufficiency* is but another term for *paralysis* of these muscles, unless congenital arrest of development be admitted." It is also claimed that, as in strabismus convergens the deviation is due to other defects than to the ever-present hypermetropia, so here, it is said, the divergence is due to some other disturbance of vision in one or both eyes.

He has "always been able to trace it" to some other cause, but admits that myopia is usually associated with these states. "It is," he says, "a fact difficult to explain that the circumstances which at one time of life determine an internal squint shall at another be fol-

lowed by the outward deviation of the eyeball. . . . A child seldom acquires an outward squint, an adult seldom acquires an internal one." In the treatment of diverging strabismus his experience is again at variance with that of most others, as he obtains "better results" here than in converging strabismus. We regret that limited space compels these hasty allusions, rather than a more extended discussion of the subject.

Chapters XIX., XX., and XXI., devoted to mechanical injuries to the eye and its appendages, are valuable, and represent the book and its author in the best light, for it is in these purely surgical aspects of the subject alone that his book will be regarded as valuable or a safe guide to the student. Of the succeeding six chapters there is but little to say, save in commendation. We thought more stress should have been laid upon sympathetic inflammation as the sequel to foreign bodies within the eye, and that for some reasons it had been better to defer the subject of artificial pupil, treated at great length in Chapter XXVI., until iritis had been studied, it being the most frequent cause of those conditions making an artificial pupil necessary.

Chapter XXVIII. is devoted to the anomalies of refraction and accommodation, which he has treated in sixty-nine pages. He has given a fair outline of this important subject; but from it alone, no one, even from the most careful study, would be prepared to correct these anomalies.

In the extraction of cataract, our author prefers the flap operation. In alluding to the peripheric linear operation of Graefe, he says it has many admirers, especially among his *personal friends*. He claims, contrary to the opinion of most operators, that it is less difficult of execution than the flap extraction, and, with a characteristic *Britonism*, insinuates the belief that its popularity is mainly due to this fact. He very justly condemns the now antiquated and dangerous operation of reclination or depression of cataract. The remaining portion of the book is taken up in the consideration of the more common defects, as diseases of the external and internal tunics of the eyeball, diseases of the optic nerve, etc. There are many points here we would desire to notice, but the limits allotted us in this review have already been exceeded. While there is so much that is good in the book, we cannot overlook its defects. In so far as it is a statement of the author's wide experience in the treatment of the purely surgical parts of his subject, the book is a valuable one; but we predict for other parts of the work a cool reception from ophthalmologists in this country. For the student it cannot compare favorably with the work of Soelberg Wells, already in the market.

S. D. RISLEY.

SELECTIONS.

EARLY HISTORY OF THE INJECTION OF MEDICINES INTO THE BLOOD.—Immediately after the discovery of the circulation of the blood by Harvey, Wren, who was then at Oxford, injected certain fluids into the veins of animals. In a letter to Sir William Petty, he states that he made the first experiment in 1656. He injected wine and ale into the vein of a dog until it became drunk, but soon after it voided them by urine. He also tried the effects of opium, scammony, and other drugs. The opium, says Oldenbrugh (Phil. Trans., 1665), stupefied but did not kill the dog. The crocus metallorum injected into the vein of another dog caused vomiting and death.

In 1667, Professor Fracassati, of Pisa, injected diluted aquafortis into the crural vein; the animal died presently,—all the blood coagulated; spirits of vitriol acted

similarly; oil of tartar, when injected, caused much suffering and great distention of the body. When opened, the blood was found fluid.

The French laid claim to the discovery in their "Medical Journals" in 1667, for a reason that one Robert de Gabets discoursed of it ten years before.

The credit of being the first to inject medicines into the human system seems to be due to Dr. Fabritius. The paper is entitled "Some new Experiments of Injection medicated Liquors into veine, together with (an account of) considerable Cures performed thereby. Communicated by Dr. Fabritius, of Dantzick. (Translated by Mr. Oldenbrugh from the original Latin)."

"As we had a great desire to try what would be the effect of the surgical experiments of injection liquors into veins, three fit subjects presenting themselves in our hospital, we thought good to make the trial upon them. But seeing little ground to hope for a manifest operation from merely altering medicines, we thought the experiment would be more convenient and conspicuous from laxatives; which made us inject by a syphon about two drams of such a kind of physic into the median vein of the right arm. The patients were these: One was a lusty robust soldier dangerously infected with the venereal disease, and suffering grievous exostoses of the bones in his arms. He, when the purgative liquor was infused into him, complained of great pains in his elbows, and the little valves of his arm swelled so visibly that it was necessary by a gentle compression of one's fingers to stroke up that swelling towards the patient's shoulders. About four hours after it began to work, not very troublesomely; and so it did the next day, insomuch that the man had five good stools after it. Without any other remedies, those protuberances were gone, nor are there any traces left of the above-mentioned disease.

"The two other trials were made upon the other sex. A married woman of 35, and a servant maid of 20 years of age, had been both of them from their birth very grievously afflicted with epileptic fits, so that there were little hopes left to cure them. They both underwent this operation, and there was injected into their veins a laxative rosin, dissolved in an anti-epileptic spirit. The first of these had gentle stools some hours after the injection, the next day the fits recurred now and then, but much milder, and are since altogether vanished. As for the other—viz., the maid, she went the same day to stool four times, and several times the next; but by going into the air, taking cold, and being careless in her food, she died.

"It is remarkable that all three vomited soon after the injection, and that excessively and frequently."—*Melbourne Medical Record*.

GLEANINGS FROM OUR EXCHANGES.

ANTISEPTIC OSTEOTOMY (*Edinburgh Medical Journal*, March, 1875).—Two years ago Professor Richard Volkmann, of Halle, introduced into his clinique the employment of the antiseptic method, and he now bears witness to the remarkable influence it has had upon the results of his operations, particularly in cases of osteotomy which are somewhat similar to artificially produced compound fractures.

He says, "The justification of operations like these undoubtedly depends entirely on the possibility of guaranteeing a successful termination. We believe that we are not assuming too much in saying that we have by degrees attained sufficient practice and experience in the antiseptic treatment of wounds, to be really able to promise such a result with certainty."

During 1874 he performed osteotomy thirteen times;

of these cases ten recovered without any suppuration at all, and the others with only the most trifling possible amount. In all the local reaction was absolutely *nil*, and in no case did the slightest redness or swelling of the soft parts take place, to say nothing of any phlegmonous inflammation.

Since the introduction of the antiseptic method, no single patient suffering from a compound fracture, in which conservative treatment was attempted, has died. These were thirty-one in number, and among them as many as nineteen compound fractures of the leg, in several instances much comminuted, and often complicated with most severe bruising and laceration of joints. Although he was working in an old and over-crowded hospital, offering the most unfavorable hygienic conditions, yet no case of pyæmia had occurred for a year and a half, although during that period about sixty major amputations had taken place.

This communication of Professor Volkmann's is of the greatest practical and scientific importance, and should be extensively noticed. The *Lancet* remarks editorially, after giving an abstract of the paper, "Such results as these deserve the widest publicity,—for criticism if they can be challenged in any way, for imitation if they cannot."

PULSATING TUMOR OF THE LEFT ORBIT, FOLLOWING FRACTURE OF THE BASE OF THE SKULL, AND CURED BY LIGATION OF THE LEFT COMMON CAROTID ARTERY (*The Lancet*, April 3, 1875).—At a recent meeting of the Royal Medical and Chirurgical Society, Mr. Walter Rivington read a lengthy paper, in which he discussed the questions of diagnosis and treatment of intra-orbital aneurism. He related the following case:

W. C., aged twenty-four, was admitted into the London Hospital in July, 1873, with a fracture of the skull. Six weeks later the patient heard a noise in his head like wind blowing, the eye gradually became prominent, pulsation of the eyeball was seen for a day or two, followed by the formation of a pulsating and thrilling tumor between the eye and the margin of the orbit. There was a bruit continuous with reinforcements, and the "bruit de pialement" could be heard at intervals. At the time of the commencement of the aneurismal symptoms, digital compression was carried out very thoroughly, without making any impression on the disease. Ligation of the carotid was discussed, but negatived at a consultation. A further trial of compression, digital, instrumental, and direct, having been made without effect, combined with veratrum, and the affection at the end of a year being decidedly aggravated, threatening extinction of vision and preventing work, an injection of five drops of a neutral watery solution of the perchloride was made; but this proving to be insufficient in quantity to cause sufficient coagulation in the dilated ophthalmic vein, and a second injection being impracticable on account of subsequent swelling, the carotid artery was tied by Mr. Rivington. This effected a cure of the disease, a slight bruit only remaining; but superficial ulceration of the cornea occurred a few days after ligation, and resulted in opacity.

The conclusions as to treatment of such cases were:—1. Belladonna, digitalis, veratrum, and ice were worthy of a trial. 2. Digital compression should always be essayed. 3. Instrumental compression was more difficult, and more likely to injure important nerves. 4. Galvano-puncture was not well suited for application to a thin-walled vein. 5. Coagulating fluids were adapted only for cases of arterio-venous aneurisms. 6. Ligation of the carotid was the remedy most generally applicable, but should not be hastily employed.

SUCCESSFUL SERIES OF OPERATIONS FOR STONE IN THE ADULT (*The Lancet*, April 3, 1875).—Sir Henry

Thompson, after briefly alluding to a series of stone-operations performed by Martineau of Norwich, and said to be the most successful on record, gives the following *résumé* of the results of his last one hundred operations:

"My present one hundred cases commenced shortly before Christmas, 1872, and includes every one operated on by myself up to the present time; it consequently represents my entire work of the last two years and a quarter. It may be worth while naming, in order to show that I have not carefully selected the term, that it commences just before the death of the late Emperor Napoleon, which is the third case of the series.

"Ninety-six were adult males, four were adult females.

"Of the ninety-six males, eighty-seven were operated on by lithotripsy and nine by lateral lithotomy.

"The mean age of the eighty-seven operated on by lithotripsy is 63½ years, the oldest being 83, the youngest 22, but only four were below 50 years.

"The mean age of the nine operated on by lithotomy was 63½ years also, their respective ages being 36, 59, 59, 61, 63, 70, 75, and 79.*

"Among the eighty-seven operated on by lithotripsy were four deaths: the ages were 61, 65, 66, and 81.

"Among the nine operated on by lithotomy were two deaths,—viz., at 61 and 63.

"Thus it will be seen that there was a total of six deaths in ninety-six patients, with a mean age of 63½, by the two operations.

"While alluding to what has been termed a run of successful cases in practice, I may observe that in this one hundred of mine there was one more remarkable than I have ever before witnessed or heard of. I had a succession of fifty-one elderly adult cases without a single death. They occurred between July, 1873, and June, 1874. These fifty-one cases (seven more than Martineau's entire adult series of all ages) had a mean age of 64 years.

"I wish to present this brief *résumé* as a fair example of what careful selection of the two operations is now capable of accomplishing for calculous patients. It is a little better than my entire average, including all my earliest experiences. What that is I hope soon to give to the profession in a complete form. I hope then to have the opportunity of recording all that I have been able to glean from an unbroken series of five hundred cases in the adult male, besides the cases of women and children."

TESTING FOR QUININE IN URINE.—The urine to be tested is rendered alkaline with ammonia, then shaken with ether, which dissolves out the quinine; the ether is poured off, a drop of hydrochloric acid is added and the ether evaporated. The minute residue is taken up in chlorine-water, and on adding ammonia the characteristic green color appears.

MISCELLANY.

FECUNDITY OF THE SHARK.—The *Union Médicale* of February 20 contained an account of a female of this species, caught by M. Lesseps, which on dissection was found to contain twelve living young ones. This viviparous character of the shark is confirmed by Dr. Moinet, an ex-naval surgeon, in a letter published in the *Union Médicale* of April 29. In it he relates that, when off the Antilles, an enormous blue shark was taken, which when

opened was found to contain seventy very lively young ones, which, when thrown into a tub of sea-water, swam about with great vivacity. In order to avoid any chance of being devoured at a later period by these interesting orphans, Dr. Moinet thought it advisable to cut short their career in a bath of boiling water. The small sharks varied from about nine to ten inches.—*London Medical Record*.

WEST VIRGINIA STATE MEDICAL SOCIETY.—The West Virginia Medical Society at their meeting at Point Pleasant, June 2, 1875, delegated Dr. W. H. Vankirk to represent their Society at the meeting of the Pennsylvania State Medical Society. The following officers were elected: *President*, Dr. A. R. Parbee, Point Pleasant; *First Vice-President*, Dr. J. O. Wall, Huntingdon; *Second Vice-President*, Dr. S. G. Shaw, Point Pleasant; *Third Vice-President*, Dr. B. F. Hoyt, Ravenswood; *Secretary*, Dr. W. M. Dent, Newburg; *Treasurer*, Dr. J. C. Hupp, Wheeling; *Censors*, Drs. Hildreth, Charter, Carpenter, Pipes, Hall, L. F. Campbell, and Bond.

The next meeting is to be held at Wheeling on the first Wednesday of June, 1876.

UNDER the title of "Two Thousand Years After; or, Talks in a Graveyard," Dr. James E. Garretson has essayed to write a continuation of Plato's world-famous discourse on the immortality of the soul, the "Phædo." The position is taken that soul is not a necessity of the human organism, and that a man may be born, may live, and may die, without being possessed of an immortal principle. Claxton, Remsen & Haffelfinger are the publishers.

DEAD HORSE.—The horse-shambles of Paris supplied the public during the third quarter of 1874 with nearly 630,000 pounds of meat, the result of the slaughter of 1555 horses, mules, and asses.

THE blue, roughened poison-bottle, so much discussed some years since in this city, has at last reached the hub of the universe. See *Boston Medical and Surgical Journal*, June 10.

It is reported that out of six thousand men sent out by the Dutch Government against the Achinese in Sumatra, no less than one thousand have died since December last from cholera and other diseases.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JUNE 8, 1875, TO JUNE 14, 1875, INCLUSIVE.

BACHE, DALLAS, SURGEON.—Granted leave of absence for two months. S. O. 114, Military Division of the Atlantic, June 7, 1875.

KNICKERBOCKER, B., ASSISTANT-SURGEON.—Assigned to temporary duty at Fort Canby, W. T., relieving Assistant-Surgeon Brooke, and upon assignment of another medical officer to duty there, to rejoin his proper station, Fort Vancouver, W. T. S. O. 69, Department of the Columbia, May 27, 1875.

DELANY, ALFRED, ASSISTANT-SURGEON.—Granted leave of absence for three months on surgeon's certificate of disability. S. O. 116, A. G. O., June 11, 1875.

STEINMETZ, W. R., ASSISTANT-SURGEON.—Assigned to duty at Cheyenne and Arapahoe Agency, Indian Territory. S. O. 91, Department of the Missouri, June 8, 1875.

MUNN, C. E., ASSISTANT-SURGEON.—Assigned to duty at Camp Robinson, Nebraska. S. O. 67, Department of the Platte, June 4, 1875.

* Only eight given.

SATURDAY, JUNE 26, 1875.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON THE USE OF ADHESIVE PLASTER IN FRACTURE OF THE PATELLA.

BY JOHN NEILL, A.M., M.D.,

Clinical Professor of Surgery in the University of Pennsylvania.

YOU have had this winter an opportunity at previous lectures of witnessing fractures of every bone in the body with the exception of the patella.

In all of these, force has been either directly or indirectly applied. You have seen bones of the arm and leg broken by direct force at the point of its application; and you have seen a fracture of the orbital plate of the frontal bone from a fall upon the back of the head, as well as a clavicle broken by a fall upon the hand where the force has not been directly applied.

But you have not seen a fracture where muscular contraction plays so important a part as in the one before us. The muscular action may be voluntary or involuntary. Gymnasts and rope-dancers break their limbs by violent exertion. I have seen a patient who had fractured his humerus by throwing a stone. The patella, however, is sometimes fractured by no extreme effort, by no unusual exertion. I saw a gentleman a few days since who fractured his patella by merely stepping from a sidewalk to the street. I also treated a patient in the Pennsylvania Hospital whose patella was fractured by a small stick, not ten inches long, striking his knee whilst riding on his dray after the manner of draymen. In such cases the muscular contraction is *involuntary*. You can readily demonstrate this contraction of the quadriceps extensor, and especially of the rectus femoris, in your own person. If you place one knee over the other, and allow the leg to hang loosely, and then forcibly strike the top of the knee with a book, the leg will immediately be extended. It is this involuntary reflex muscular action which causes fractures of the patella to occur from such apparently trivial causes. Alighting on an irregular piece of ground, the attempt to save oneself may produce such a fracture. Of course the patella may be broken by a direct blow, a bullet, or by machinery, but such are generally compound fractures. In simple transverse fractures of the patella the force is always more or less the result of involuntary muscular contraction.

I will not enter into the discussion between the English surgeons who formerly stated that the force was *always* immediate and direct, and the French surgeons who declared that every fracture of the patella was the result of involuntary muscular action; but by experimenting for yourselves in the dissecting-room you will have difficulty in producing this fracture unless you use some instrument, such as a hatchet.

Now, in this hearty, hale young man, the acci-

dent occurred two days ago. He was wrestling with a friend, and, as he was going under, his knee touched the ground, and he suddenly became completely disabled, fell, and was unable to walk.

There is some swelling, but, as I press my fingers between the fragments, you can easily see the interstice. This is not a trifling injury, though he seems to suffer no pain or inconvenience as he lies in bed; but unless he is properly treated he will not only be lame for life, but his locomotion will be seriously interfered with, especially in going up-stairs.

At the same time, understand that bony union will hardly take place. So rarely do the fragments unite by bone that some surgeons doubt whether there ever was a bony union. Many specimens which have been supposed to be united by bone have not stood the test of being boiled and sawed in sections. I never saw but one perfect specimen, which, I am sorry to say, I have either mislaid, lost, or loaned. I hope it will some day re-appear. The specimen was well boiled, and the interstice found to be completely filled up with new bone, increasing the longitudinal measurement at least one-third.

In the living subject one often thinks that the union is bony because we cannot move one fragment upon the other, and the patient thinks so too. A man stopped me in the street a few days ago, and, finding that I did not recognize him, said, "You will know me by my knee: I have a bony union which you treated at the college on Ninth Street." I recalled his case, and examined his knee, and could feel no separation of fragments.
